Contribution of the Microenvironment in Bone Resident Cancer:
the Role of Thrombospondin-1 in Bone and Risk Loci Contributing to Multiple Myeloma

by

Sarah R. Amend

A dissertation presented to the
Graduate School of Arts & Sciences
of Washington University in
partial fulfillment of the
requirements for the degree
of Doctor of Philosophy

August 2014
St. Louis, Missouri

Table of Contents

List of Figures	iv
List of Tables	vi
List of Abbreviations	vii

List of Abbreviations

BIP – benign idiopathic paraproteinemia
BMM – bone marrow macrophage
BMSC – bone marrow stromal cell
ECM – extracellular matrix
MGUS – monoclonal gammopathy of undetermined significance
MM – multiple myeloma
NCP – non-collagenous protein
NO – nitric oxide
NOS – nitric oxide synthase
OB – osteoblast
OC – osteoclast
SNP – single nucleotide polymorphism
SPEP – serum protein electrophoresis
TAM – tumor associated macrophage
TSP1 – Thrombospondin-1
WGAA – whole genome association study

Acknowledgements

My research was funded by the National Institutes of Health / National Cancer Institute (pre-doctoral fellowship 1F31CA174096-01A1), the National Institutes of Health / National Heart, Lung, and Blood Institute (training grant 5T32HL007088), and the Lucille P. Markey Special Emphasis Pathway in Human Pathobiology at Washington University School of Medicine.

I owe a debt of gratitude to my thesis advisor, Katherine Weilbecher. Kathy, you pushed me to be independent, encouraged creative thinking, and showed unwavering confidence in my abilities and thought processes. Thank you for your patience, your sense of humor, and your dedication to your trainees.

One of my major graduate projects was possible because of Michael Tomasson's confidence in my skills and ideas. Thank you for teaching me to be a better communicator and collaborator.

Thank you to all of the Weilbaecher lab members during my tenure in the lab, but most especially Xinming Su, Jingyu "Jerry" Xiang, Alison Esser, Yalin Xu, and Michael Ross. I couldn't ask for better lab mates. Special thanks to Michelle: voice of reason, math-checker extraordinaire, and, most especially, friend.

My thesis committee has been wonderful: Deb Novack, Bill Frazier, Ken Blumer, and John DiPersio. Thank you for your guidance and thoughtful feedback.

To the members of the Experimental Skeletal Biology group, most especially Steve Teitelbaum, Deb Novack, Roberta Faccio, Roberto Civitelli, and Matt Silva: your suggestions and help have been invaluable. To the myeloma and MGUS translational research group, most especially Jacob Paasch, Ravi Vij, and Graham Colditz, thank you for your feedback and practical support.

My graduate school experience certainly wouldn't have been as successful (or as fun) without my friends. Special recognition goes to the Too Cute Tuesday group. Thanks to Danka, for always being there, when I knew I needed it and when I didn't; to Anne, for everything, most especially pizza and beer night; and to Emily, for your love and encouragement. Ben, Katie, and Renee: thanks for making sure I was more than "just" a scientist. Brian, thank you for your patient support. Ida, thanks for entrusting me with your horses and allowing me the opportunity to pursue my other passion.

Finally, I couldn't have done this without my parents, Elisabeth and Fred Amend. Mum, thanks for helping me with the many top-crisis-secrets and for sharing my love of science with everyone you know. Dad, your reminders that "even bad-news data tells you something new!" have gotten me through more experiments than you realize. Thank you both for your unconditional confidence and constant support.

This work is dedicated to the teachers who encouraged me to pursue a career in science,
to ask challenging questions, and to always be excited about discovery.

Michael Tomasson, Co-Chair

Cancer growth in bone, a defining characteristic of multiple myeloma and common in many solid tumors including breast and prostate cancer, is characterized by the active participation of host microenvironment cells. Tumor cells stimulate the vicious cycle through stimulation of bone remodeling by osteoclasts and osteoblasts, resulting in increased release of growth factors and cytokines to further promote local tumor growth. Notably, cancer cells are unable to remodel bone independently, and require the metabolically active bone cells for this support.

A specific role for the bone microenvironment in mediating tumor growth was first discussed in 1889 with the introduction of Paget's seed-and-soil hypothesis that tumor cells will only grow in a favorable microenvironment. This dissertation is focused on investigating the properties of a "congenial soil." In Chapter 2 we discuss the role of bone-resident Thrombospondin-1 (TSP1), a glycoprotein with well-documented roles in promoting cancer growth. Chapter 3 is focused on the identification of genes conferring inherited susceptibility to

multiple myeloma that participate both in malignant cells and in host supportive cells.

TSP1 is a large matricellular protein that interacts $\beta 3$ integrin, CD47, and other receptors to regulate cell migration, adhesion, and proliferation with effects on tumor angiogenesis, inflammation, and wound healing. We examined the role of TSP1 in the bone microenvironment. TSP1^{-/-} mice had increased trabecular bone volume and increased cortical bone area and thickness compared to wild type controls. Surprisingly, TSP1^{-/-} mouse bones did not resist bending as much as anticipated, and we confirmed a bone materials defect, indicating that TSP1 was important for maintaining bone quality. In addition to the mechanical defects, TSP1^{-/-} mice had decreased serum CTX compared to controls, indicating an osteoclast defect. Primary osteoclast cultures require TSP1 at early stages of osteoclastogenesis, though exogenous TSP1 is dispensable at later stages of maturation. Interestingly, we found that TSP1-deplete osteoclast cultures had a significant and dramatic increase in inducible nitric oxide synthase (iNOS) expression. Moreover, upon administration of a NOS inhibitor to mice, the TSP1^{-/-} bone resorption defect was rescued to wild type levels. To test whether osteoblast-deposited bone-resident TSP1 inhibits early osteoclast NO signaling, we plated osteoclasts on either wild type or TSP1^{-/-} bone and found that only wild type bone was sufficient to block iNOS expression. Thus, we conclude that TSP1 is a paracrine signaling molecule that couples OB activity to OC formation and targeting of the TSP1 signaling pathway, currently under investigation for treating cancer and modulating blood pressure, may have additional effects on bone.

The second part of this dissertation focuses on host susceptibility to multiple myeloma (MM) and its requisite precursor, monoclonal gammopathy of undetermined significance (MGUS). The C57Bl/KaLwRij (KaLwRij) mouse strain has increased susceptibility to benign idiopathic paraproteinemia (BIP), analogous to human MGUS, and is a common mouse model

for the disease. Following immunization, KaLwRij mice developed a sustained M-spike at a higher frequency than 12 other genetically diverse mouse strains, most notably, the highly related C57Bl/6J (B6) strain. To query the genetic basis for BIP susceptibility in KaLwRij mice, we completed SNP analysis to identify variation between KaLwRij and B6. We found that KaLwRij is a unique inbred strain, completely distinct from the closely related B6. We identified several thousand variants between KaLwRij and B6 and compiled a candidate gene list of 419 genes. To ensure that we would pursue genes applicable to human disease, we completed whole genome association analysis between MM patients and healthy controls and identified SNPs located in 180 gene loci. Combining these two gene sets resulted in a candidate gene list of 5 genes, one of which, *Samsn1*, is annotated as a negative regulator of B-cell activation. Upon closer examination of the *Samsn1* locus, we found that KaLwRij harbored a germline deletion of all coding exons of the gene, resulting in absent RNA and protein expression. Consistent with the published role of SAMS1 in genetically deficient mice, KaLwRij mice had enhanced B-cell function as evaluated by B-cell proliferation in primary culture and in vivo IgG2b response. To investigate the role of *Samsn1* in host cells, we profiled *Samsn1* expression in bone microenvironment cells and found that macrophages were high expressers. KaLwRij macrophages had enhanced expression of polarization markers, suggesting that they are pre-activated under homeostatic conditions. Further, we found that KaLwRij macrophages stimulated to a pro-tumorigenic M2 polarization promoted 5TG myeloma tumor growth more than B6 control macrophages in mice. In conclusion, we identified candidate gene lists underlying murine and human susceptibility to MGUS and myeloma. Specifically, we found that *Samsn1* contributes to KaLwRij susceptibility to BIP, and likely to human MGUS, through effects in pre-malignant B-cells and in macrophages.

Chapter 1
Introduction

The seed and soil hypothesis of metastasis

Metastasis is the dissemination of primary tumor cells to a distant site. In 1889, Stephen Paget, a physician in the West London hospital, analyzed the autopsies of 735 fatal breast cancer patients. He noted that secondary growth was more often seen in some organs than others, even in those with the same potential for metastasis (e.g. liver vs. spleen). Furthermore, he noted that “the bones [of breast cancer patients] suffer in a special way,” more than would be predicted based on the circulation of tumor cells alone, based on evidence from other cancer types (Paget, 1889).

These observations led to his proposal of the “seed and soil” hypothesis: “when a plant goes to seed, its seeds are carried in all directions, but they can only live and grow if they fall on congenial soil.” Cancer biologists, then, must be “scientific botanists,” concerned not just with the malignant seed, but also with the “properties of the soil” that make up a favorable tumor microenvironment (Paget, 1889).

The goal of this thesis is to contribute to the understanding of the “congenial soil.” First, we will address the role of the antiangiogenic Thrombospondin-1 in the “fertile soil” of bone, a common site of metastasis. Second, we will identify genetic risk loci that confer whole-host “congeniality” to multiple myeloma (MM) and its precursor syndrome monoclonal gammopathy of undetermined significance (MGUS).

Part I: The role of the bone microenvironment in metastasis.

Homeostatic bone remodeling requires coupled bone formation and destruction

Bone is a dynamic connective organ that, together with the cartilage, comprises the skeleton and provides mechanical, protective, and metabolic support for the rest of the body. Cancellous bone is made of a lattice of trabeculae localized to the metaphysis of long bones with high surface area for mineral metabolism. Cortical bone forms the outer shell of the metaphysis and the diaphysis (shaft) of long bones to provide mechanical support. The bone marrow found in the marrow space formed by the cortical bone is made up of hematopoietic and stromal cells that give rise to blood cells, platelets, endothelial cells, fibroblasts, adipocytes, osteoblasts (OBs), and osteoclasts (OCs) (Baron, 1996).

The bone matrix is composed of two compartments: osteoid (primarily collagen type I fibers—90%, and non-collagenous proteins—10%) and mineral (calcium-phosphate hydroxyapatite crystals). The numerous noncollagenous proteins include growth factors, proteoglycans, and adhesion molecules. These molecules contribute to maintenance of homeostatic bone remodeling, promoting cell attachment, differentiation, and growth of bone remodeling cells. In addition, some molecules aid in osteoid and mineral matrix organization, directly influencing bone strength.

Bone-forming OB arise from mesenchymal stem cells and express specific markers during differentiation including Runx2, alkaline phosphatase, osteonectin, and osteocalcin, useful for tracking OB formation in an experimental setting. To form bone, OBs deposit collagen fibers to form the extracellular matrix that is subsequently calcified with hydroxyapatite crystals. Osteoid also contains non-collagenous proteins secreted by the OBs including

thrombospondin-1 (TSP1), BMPs, IGFs, and TGF β that play diverse roles in maintaining matrix structure and as signaling molecules to promote adhesion, survival, and differentiation of cells within the bone marrow (Puzas, 1996). OBs also directly promote OC formation through pre-OB secretion of MCSF and expression of RANKL, key cytokines necessary for osteoclastogenesis.

OCs arise from the MCSF- and RANKL-dependent fusion of macrophages. Following fusion, pre-OCs polarize and form the characteristic ruffled membrane necessary for bone resorption. OCs form a contractile actin ring to create a highly acidic sealing zone, the site of bone resorption (Baron, 1996; Novack and Teitelbaum, 2008). Cells committed to the OC lineage are TRAP⁺, useful for in vitro staining. Furthermore, each stage of OC formation is characterized by a unique gene expression signature: early OC precursors express N-FATc1, fusing OC express DC-STAMP and CD47, polarized cells express $\alpha\beta$ 3 integrin, and mature resorbing cells express Cathepsin K. Dissolving of the mineral and underlying matrix releases growth factors and cytokines essential for OB activity, thus recruiting bone formation to a site of recent bone destruction.

Bone remodeling is a tightly regulated process that requires the coupled activity of bone forming OBs and bone resorbing OCs. Bone remodeling is necessary to preserve the integrity of the skeleton and to maintain calcium and phosphate levels (Baron, 1996; Hadjidakis and Androulakis, 2006). Misregulation of the basal bone remodeling, as in osteoporosis or bone metastasis, leads to decreased bone integrity, resulting in hypercalcemia, nerve-compression, and pathologic fracture.

Bone is a favorable microenvironment for metastatic invasion and growth

Bone metastasis is common to many cancers, including breast (70%), prostate (70%) and lung (35%), and bone disease is characteristic of multiple myeloma (Coleman, 2001; Lipton, 2004; Mundy, 2002). The consequences of bone metastases are devastating and cause pain, pathologic fracture, spinal cord and other nerve-compression syndromes, and life-threatening hypercalcemia (Roodman, 2004). Both osteolytic lesions and osteoblastic bone metastases are associated with increased OC activity and disrupted bone micro-architecture (Coleman et al., 2005; Lipton et al., 2001). Notably, while cancer cells are unable to resorb bone independently, they secrete soluble factors that promote bone remodeling resulting in the release of additional bone matrix-bound growth factors which further activates OCs and OBs and promotes tumor growth (Bendre et al., 2003; Clines and Guise, 2008; Guise et al., 2006; Hirbe et al., 2006; Hirbe et al., 2007; Kakonen et al., 2002; Kingsley et al., 2007; Kozlow and Guise, 2005; Mundy, 2002; Pfeilschifter et al., 1987; Roodman, 2004; Yin et al., 1999). This process of pathologic induction of bone remodeling by the cancer cells results in a “vicious cycle” of tumor growth and bone destruction (**Figure 1.1**). Anti-resorptive therapy, e.g. with bisphosphonates or denosumab, significantly decreases skeletal complications of cancer and is a standard of care for patients with bone metastases (Body et al., 2009; Fizazi et al., 2009; Hamdy, 2008; Hirbe et al., 2006; Roodman, 2004).

Integrins play a critical role in bone metastasis in both tumor cells and host stromal cells

The site of metastasis is tumor cell specific depending on adhesion molecule and chemokine receptor expression profiles of both the cancer cell and the host organ cells (Kang et al., 2003; Marcellini et al., 2006; Wei et al., 2005; Yoneda, 2000). At the metastatic site, normal

physiology is changed towards increased secretion of cytokines and activation of adhesion molecules to support recruitment, survival, and growth of tumor cells. Integrins expressed by tumor cells, in concert with bone microenvironment chemokine secretion and further adhesion molecule activation, determines the osteotropic characteristics of metastasizing cancer cells and represent an ideal target for skeletal metastatic cancer therapy.

Integrins are heterodimeric transmembrane glycoproteins that facilitate cell-cell and cell-extracellular matrix adhesion and cell migration (Schwartz et al., 1995). Integrins recruit many intracellular signaling molecules and can activate survival, proliferation, and motility signaling pathways (Hynes, 1992). Tumor cells localize to specific tissues through integrin-mediated contacts with extracellular matrix and stromal cells. Integrin expression and signaling are perturbed in cancer cells, allowing them to “escape” from cell-cell and cell-matrix tethers, invade, migrate, and colonize within new tissues and matrices. Integrin signaling through $\alpha\text{v}\beta 3$ and VLA-4 on tumor cells promotes tumor metastasis to and proliferation in the bone microenvironment. As described above, misregulated OC-mediated bone resorption is a hallmark of bone metastasis and promotes tumor expansion in the marrow space. $\alpha\text{v}\beta 3$ integrins are critical for OC function and development (Faccio et al., 1998; Faccio et al., 2003; Feng et al., 2001), and $\beta 3^{-/-}$ mice have reduced tumor burden in bone and are protected from tumor-associated osteolysis due to defective OC (Bakewell et al., 2003; Morgan et al., 2009)

Integrin-mediated cell signaling plays a critical role in many of these processes during bone metastasis, including platelet aggregation ($\alpha\text{IIb}\beta 3$), hematopoietic/immune cell mobilization (VLA-4, osteopontin, TSP1), neoangiogenesis ($\alpha\text{v}\beta 3$, $\alpha\text{v}\beta 5$, $\alpha 6\beta 4$, $\beta 1$ integrins, TSP1, CD47) and stromal function (osteopontin, VLA-4) (**Figure 1.2**). The mechanisms by which integrin signaling mediates the pathogenesis of bone metastasis, both from the tumor cell

and the host microenvironment, is an area of active research. Integrin pathway signaling is critical in the pathogenesis of bone metastasis at many stages and further study to define integrin dysregulation by cancer cells will yield new therapeutic targets for the prevention and treatment of bone metastasis.

Integrin signaling is critical for cell adhesion and survival

There are 8 beta and 18 alpha integrin subunits that assemble into 24 different known combinations in different cell types, each characterized by distinct ligand binding specificities, signaling abilities, and regulatory mechanisms(Hynes, 2002). Integrins are activated by conformational changes in the integrin extracellular domains (“inside-out” signaling). When the integrin α and β subunit cytoplasmic and transmembrane domains remain closely juxtaposed, the extracellular domains are held in a closed conformation. Activation by intracellular signals to the cytoplasmic tails results in separation of the α and β cytoplasmic and transmembrane domains and exposure of the extracellular ligand binding domain (Shattil et al., 2010) (“inside-out” signaling). In addition to activation by inside-out signaling, ligand binding and integrin clustering can be significantly modulated by growth factor receptor interactions and other integrin interacting proteins, as reviewed in (Desgrosellier and Cheresh; Hynes, 2002; Shattil et al., 2010). The open conformation facilitates high affinity ligand binding and triggers integrin-mediated cell signaling cascades (“outside-in” signaling) (Offermanns, 2006; Qin et al., 2004), critical for growth, migration, adhesion, and survival.

Maintaining adhesion to the extracellular matrix, in part through integrin signaling, is critical to cell survival (Frisch and Screaton, 2001). Altered cell-cell or cell-matrix interactions can result in disruption of downstream survival signaling and anchorage-dependent non-

transformed cells undergo anoikis (Frisch and Screaton, 2001). Under normal conditions, because each cell type expresses a unique set of integrins that recognize underlying extracellular matrix ligands, this form of apoptosis ensures that detached cells do not colonize inappropriate locations (Frisch and Screaton, 2001). Cells that resist anoikis, such as metastatic cells, take advantage of aberrant integrin expression that enables the cell to adhere to a novel extracellular matrix (Bissell and Radisky, 2001) and colonize a distant site.

Integrin signaling in tumor cells that metastasize to bone

Tumor progression, invasion, and metastasis require the activity of many adhesion proteins, including the integrin superfamily. At each stage of cancer progression, subsets of integrin heterodimers are activated, providing the necessary signaling pathways for adhesion, migration, and cell survival. Metastatic tumor cells show differential integrin heterodimerization and activation compared to non-metastatic tumor cells that enable the cell to home to and colonize in a metastatic site, such as the bone marrow cavity (Edlund et al., 2001; Yoneda, 2000). In order for primary epithelial cancers to metastasize, the tumor cells must become resistant to anoikis and detach from the primary tumor site extracellular matrix, enter the vasculature, and eventually colonize a distant site. Upon reaching a successful metastatic site, however, tumor cells use both anoikis and anoikis-resistance to their advantage, in some cases forming micro-metastases that are resistant to cancer treatment via integrin binding to the underlying bone matrix as reviewed in (Clezzardin, 2009). In addition to evading apoptosis, tumor cells must also form interactions between the tumor cell and bone stroma to establish and maintain skeletal metastasis.

The $\beta 3$ integrin signaling pathway has been implicated in tumor cell-host bone stroma interactions during bone metastasis and tumor growth in bone (**Figure 1.2**). Breast cancer cells that overexpress $\alpha v\beta 3$ have increased levels of bone metastasis and associated tumor burden and osteolysis (Nakamura et al., 2007; Pecher et al., 2002; Sloan et al., 2006; Van der Velde-Zimmermann et al., 1997; Zhao et al., 2007). This overexpression of $\alpha v\beta 3$ in the tumor cells leads to increased tumor cell adhesion, migration, and invasion to bone as well as enhanced OC recruitment within the bone microenvironment (Pecher et al., 2002; Sloan et al., 2006), implicating a role of tumor-specific $\alpha v\beta 3$ expression in breast cancer metastasis to bone as well as tumor-associated osteolysis. Likewise, in prostate cancer cells, active $\alpha v\beta 3$ is necessary for the adherence and migration to bone matrix proteins at early stages of skeletal metastasis. This tumor cell $\alpha v\beta 3$ integrin expression allows cancer cells to adhere to the bone matrix and interact directly with the native bone cells, OBs and OCs, as well as with the bone matrix itself (Nakamura et al., 2007).

CD47 and TSP1 augment $\alpha v\beta 3$ integrin signaling

$\beta 3$ integrins are activated upon binding to an Arg-Gly-Asp (RGD) protein motif, contained in many extracellular matrix proteins including vitronectin, fibronectin, osteopontin, bone sialoprotein, and TSP1, among others. Importantly, integrin associated protein CD47 augments integrin activation and affects the ability of $\alpha v\beta 3$ integrin to cluster upon ligand binding (Brown and Frazier, 2001). CD47 augments $\beta 3$ integrin-dependent adhesion, with CD47-deficient $\beta 3$ -expressing cells showing decreased adhesion to vitronectin (Lindberg et al., 1996). Notably, TSP1 ligation of CD47 further enhances adhesion (Gao et al., 1996), suggesting that TSP1-binding of CD47 mediates the enhancement of $\beta 3$ function. Pertussis toxin inhibits

these effects, providing evidence that the mechanism likely involves Gai GTPase activity (Frazier et al., 1999; Green et al., 1999). Investigation of the role of TSP1 in the bone microenvironment will be discussed in **Chapter 2**.

$\alpha v\beta 3$ integrin and thrombospondin-1 regulate tumor angiogenesis

Tumor neovascularization is essential for tumor growth and metastasis, providing the cancer cells with host nutrients and access to the circulation for the dissemination for metastatic cells. The ability of tumor cells to activate the normally quiescent vasculature is proposed to be controlled by an “angiogenic switch” mechanism, whereby tumor or stromal cells induce changes in the relative balance of inducers (VEGF, TGF β) and inhibitors (TSP-1) of angiogenesis (reviewed in (Desgrosellier and Cheresch; Hanahan and Weinberg, 2000; Hodivala-Dilke, 2008; Hood and Cheresch, 2002; Silva et al., 2008; Stupack and Cheresch, 2004)).

Many integrins have been implicated in angiogenesis, but one of the best characterized is $\alpha v\beta 3$. Integrin $\alpha v\beta 3$ is highly expressed on tumor-associated vasculature, and angiogenesis is inhibited with $\beta 3$ neutralizing antibodies. Interestingly, however, $\beta 3^{-/-}$ mice have enhanced (not reduced) tumor-associated angiogenesis in subcutaneous tumors (Reynolds et al., 2002). In $\beta 3$ floxed mice crossed with endothelial-specific Cre mice, depletion of $\beta 3$ integrin in endothelial cells inhibits angiogenesis and tumor growth in a preventative setting, but not in established tumors. Moreover, these tumor effects are transient, and long-term endothelial cell $\beta 3$ deletion is ineffective to reduce angiogenesis (Steri et al., 2014). Reports that low dose integrin antagonists can increase tumor growth and angiogenesis while higher doses suppress tumor growth and angiogenesis (Reynolds et al., 2009) (Carmeliet, 2002; Martin et al., 2002; Wang et al., 2001;

Zhao et al., 2005) further underscore the complexity of targeting $\beta 3$ integrins for angiogenesis and cancer therapy.

In some scenarios, $\beta 3$ integrin influences angiogenesis through interactions with ligand TSP1. TSP1 was the first identified endogenous anti-angiogenic factor (Isenberg et al., 2007a) and plays a role in neoangiogenesis in endothelial cells and platelets through its interactions with CD47 and $\beta 3$ integrin. In numerous studies, TSP1 has tumor suppressing effects in the tumor microenvironment and many tumors have low expression of TSP1 (reviewed in (Kazerounian et al., 2008)). TSP1^{-/-} mice have increased tumor burden and tumor-associated vasculature in a primary tumor model, while mice that over-express TSP1 have delayed tumor growth and reduced tumor-associated vasculature (Rodriguez-Manzanque et al., 2001). In contrast, other studies demonstrate a role for TSP1 in promoting tumor progression (Dias et al., 2012; John et al., 2010; Tuszynski et al., 1987) in part through TSP1 stimulation of endothelial cell migration through interactions with the $\alpha 6$ integrin pathway (Dias et al., 2012; John et al., 2010). Thus, TSP-1 can play both pro- and anti-angiogenic roles, depending on its specific integrin interaction.

The role of $\alpha v\beta 3$ integrin in tumor-associated angiogenesis is complex, not only involving integrin-ligand interactions and associated signaling pathways, but also specific temporal regulation and indirect effects through proteins such as TSP1, and are important for the progression of angiogenesis and eventual metastasis.

Integrin $\alpha v\beta 3$ is necessary for osteoclast function and plays a key role in bone metastasis

Bone invading metastatic tumor cells co-opt integrin signaling pathways that enhance OC function and recruitment. As part of bone remodeling, OC bind to the bone matrix, form an actin

ring mediated sealing zone, secrete enzymes and acid to degrade bone, and then migrate to a new site. Each of these functions is regulated in part by integrins located on the membrane surface of the OC, interacting with neighboring cells and with the extracellular matrix (Teitelbaum and Ross, 2003).

$\alpha\text{v}\beta 3$ is the predominant integrin found on OCs and plays roles in multiple components of osteoclastogenesis and resorption (Novack and Teitelbaum 2008; Ross and Teitelbaum 2005). $\alpha\text{v}\beta 3$ is responsible for mediating OC::bone matrix recognition (Crippes et al., 1996; Liapis et al., 1996; Ross et al., 1993; Zamboni Zallone et al., 1989), adhesion (Chellaiah, 2006; Ross et al., 1993), formation of the ruffled border, and overall organization of the cytoskeleton (Faccio et al., 2003; McHugh, 2000; Rucci et al., 2005; Zhang et al., 2000). Antibody inhibition of $\alpha\text{v}\beta 3$ inhibits OC attachment to the bone matrix and OC-mediated bone resorption (Ross et al., 1993). In addition, $\beta 3^{-/-}$ have defective OC function (McHugh, 2000) and are protected from tumor associated osteolysis (Bakewell et al., 2003).

Integrin $\alpha\text{v}\beta 3$ ligand CD47 also plays important roles in OC formation and tumor-associated osteolysis, both through augmenting $\beta 3$ activity, and in an integrin-independent manner. $\text{CD47}^{-/-}$ mice have increased bone volume due in part to reduced OC number and function (Koskinen et al., 2013; Uluckan et al., 2009), and $\text{CD47}^{-/-}$ mice are partially protected from tumor-associated osteolysis (Uluckan et al., 2009). CD47 in OC include binding to $\text{SIRP}\alpha$ in hematopoietic cells is an important “self-signal” to prevent phagocytosis. $\text{CD47}:\text{SIRP}\alpha$ binding is also important for macrophage fusion, an early event in OC formation (Han et al., 2000; Lundberg et al., 2007; Vignery, 2005). Interestingly, $\text{CD47}^{-/-}$ OCs have increased levels of inducible nitric oxide synthase and the $\text{CD47}^{-/-}$ OC formation defect is rescued in vitro through blockade of nitric oxide signaling (Uluckan et al., 2009). Notably, in other cell types

TSP1-CD47 binding inhibits nitric oxide signaling; we will investigate the role of TSP1 in nitric oxide mediated regulation of OC in **Chapter 2**.

OC targeted therapy is a standard of care for the treatment of bone metastasis and myeloma bone disease. Tumor cells recruit OCs resulting in bone destruction and pain (Clohisey and Ramnaraine, 1998; Honore et al., 2000; Mundy, 2002). Because of its known role in OC function and its high expression in skeletal metastatic tumors as discussed above, much research has focused on $\alpha v\beta 3$ integrin and its ligands in bone. Elucidating the role of $\beta 3$ integrin pathway member TSP1 is the subject of **Chapter 2**.

$\beta 3$ -/-, CD47-/-, and TSP1-/- mice have phenotypic overlap suggesting a common pathway

Mice with genetic deficiency in individual components of the $\alpha v\beta 3$ pathway, including $\beta 3$, CD47, and TSP1, show phenotypic overlap in characteristics essential for bone metastasis (**Table 1.1**). Importantly, both $\beta 3$ -/- and TSP1-/- mice have increased primary tumor growth and neoangiogenesis (Reynolds et al., 2002; Rodriguez-Manzaneque et al., 2001), while CD47-/- mice have decreased tumor burden with no apparent effect on angiogenesis, suggesting that the $\beta 3$ -CD47 signaling pathway may not participate in primary tumorigenesis. In the bone microenvironment, however, $\beta 3$ -/- and CD47-/- mice both have increased bone volume and decreased tumor-associated osteolysis (Bakewell et al., 2003; Uluckan et al., 2009), largely due to decreased OC activity. While the TSP1-/- mouse bone phenotype has not been fully evaluated, there is some evidence implicating TSP1 in OC activity (Carron et al., 2000; Carron et al., 1995).

Together, these data led us to hypothesize that the $\beta 3$ – CD47 – TSP1 signaling axis is important in the bone microenvironment, both under homeostatic and pathologic states.

Investigation of the role of TSP1 in the bone is the topic of **Chapter 2**.

Thrombospondin-1 is expressed in the bone matrix, but its role remains unknown

TSP1 is a large matricellular glycoprotein (350 kDa) that is ligand for at least 11 unique receptors, including $\alpha v\beta 3$ integrin, CD47, and CD36, as well as many extracellular matrix proteins, including collagen, calcium, and osteopontin, among others. It is expressed and secreted by all vascular, endothelial, and hematopoietic cells, but is most highly secreted by activated platelets as part of wound healing. As a matricellular protein, TSP1 has dual function, both as a member of the ECM and as a signaling molecule.

TSP1 deficient mice are reported to have mild spine deformation (Crawford et al., 1998) and mild growth plate cartilage disorganization (Posey et al., 2008) but detailed analysis of bone has not been reported. TSP1 is expressed by OBs and is present in osteoid and mineralized bone matrix (Grzesik and Robey, 1994; Kannus et al., 1998; Robey et al., 1989) where it is directly deposited by bone-forming OBs (Cleazardin et al., 1989; Robey et al., 1989). TSP1 participates in OB differentiation in part through activation of latent TGF- β (Bailey Dubose et al., 2012; Ueno et al., 2006), and TSP1 receptors CD47 and CD36 also regulate OB (Kevorkova et al., 2013; Koskinen et al., 2013). TSP1 has been implicated in OC activity, but its mechanism of action remains unknown (Carron et al., 1995). TSP1-CD47 interactions play a role in the formation of multiple myeloma-dendritic cell fusions with bone-resorbing capacity (Kukreja et al., 2009), and TSP1-CD36 ligation can promote osteoclastic resorption on dentine slices (Carron et al., 2000). Together these data led us to hypothesize that OB-secreted TSP1 sequestered in bone matrix will

modulate OC function thereby coupling OB activity to OC formation which we will investigate in **Chapter 2**.

Nitric oxide signaling modulates endothelial cell and osteoclast activity

Nitric oxide (NO) is synthesized by NO synthases (NOSs): eNOS and nNOS synthesize low levels of NO (Tsutsui, 2004) while higher levels are produced by iNOS, induced upon inflammatory cell activation (**Figure 1.2**) (Ridnour et al., 2005; Ridnour et al., 2006). NO binds sGC to catalyze the reaction of cGMP (Roy and Garthwaite, 2006), responsible for regulating signaling that controls proliferation, migration, cell cycle and apoptosis (Thomas et al., 2008). NO exerts a biphasic effect with low (<10 nM) levels of NO necessary for maintaining normal cell function (Isenberg et al., 2007b), while high (>100 nM) levels of NO are toxic (Lau, 2003) (**Figure 1.3**). Thus, tight regulation of NO is critical for normal cell function and unregulated increases in NO is typical of many pathologic conditions, including cancer, and can lead to cell toxicity or disrupted cell function.

NO signaling is a critical signaling pathway during homeostatic bone resorption. Upon stimulation with RANKL, OC precursors upregulate iNOS expression through an NF κ B-dependent mechanism and the subsequent high NO concentration inhibits further OC formation (Zheng et al., 2006). iNOS deficient bone marrow macrophages show increased OC formation and resorption (Zheng et al., 2006). Misregulation of NO signaling, therefore, may lead to aberrant bone remodeling, compromising skeletal integrity.

TSP1 is a regulator of NO in endothelial cells, platelets, and vascular smooth muscle cells (Bergseth et al., 2000; Chen et al., 2000). Notably, only TSP1 receptors CD36 and CD47 have been implicated in NO regulation. TSP1^{-/-} mice show elevated levels of endothelial cell

cGMP compared to wild type, and primary cultures show increased proliferation, migration, and adhesion (Isenberg et al., 2005). NO-stimulated endothelial cells and vascular smooth muscle cells have increased proliferation and migration and elevated cGMP (Isenberg et al., 2005). These responses are blocked upon addition of TSP1, CD47-binding peptide, or CD36-binding peptide (Isenberg et al., 2005). Vascular outgrowth is increased in TSP1^{-/-} mice, an effect that is augmented with NO stimulation (Isenberg et al., 2006). Interestingly, while addition of TSP1 inhibits the NO-stimulated vascular outgrowth in CD36^{-/-} mice, it has no effect in CD47^{-/-} mice (Isenberg et al., 2006), indicating that CD47 is necessary for NO-mediated endothelial cell function. Despite identification of CD36 as a regulator of eNOS (Isenberg et al., 2007b), the direct mechanism of action for CD47 inhibition of NO has not been identified. Our lab reported that CD47 suppression of NO signaling in OCs plays an important role in pathologic osteolysis (Uluckan et al., 2009), but the CD47-activating ligand in OCs has not been defined. We will explore the role of TSP1-regulation of NO signaling in OC in **Chapter 2**. We hypothesize that TSP1 is a negative regulator of NO signaling in OC, promoting early stages of OC formation.

Goals of the present study

The seed-and-soil hypothesis of cancer metastasis has been accepted for decades, and the field of cancer biology acknowledges the necessity of host support for tumor growth. While many molecules have been implicated in host-cell support of tumor growth, the components of “congenial soil” remain incomplete. Therapeutic targeting of the host cells, specifically the uncoupling of the “vicious cycle” within the bone microenvironment, represents a promising site of intervention for the treatment of bone metastasis.

In **Chapter 2**, we elucidate the role of potent anti-angiogenic TSP1 in bone in order to better understand the impacts of TSP1-pathway directed therapeutics. While many receptors of TSP1 are known to be important for bone integrity, both in the bone matrix and in metabolically active bone cells, the role of the matricellular ligand is unclear. We demonstrated that TSP1 played both structural and signaling roles to maintain bone homeostasis. Using TSP1-null mice, we showed that TSP1 contributed to bone quality and that it was essential for OC formation. We found that pharmacologic inhibition of NO signaling in TSP1-/- mice restored OC activity, placing TSP1 upstream of NO regulation of OC formation. Importantly, we present strong evidence for TSP1 as a paracrine signaling molecule, coupling OB activity to OC formation, thus building upon the literature of critical bone remodeling factors.

Part II: Genetic susceptibility to monoclonal gammopathy of undetermined significance, the requisite precursor to multiple myeloma

Monoclonal gammopathy of undetermined significance is a common disorder of aging

Monoclonal gammopathy of undetermined significance (MGUS) is a common syndrome of aging, with a prevalence of 3.2 – 5.2 percent in 50 – 70 year olds, respectively (Kyle et al., 2006; Landgren et al., 2009). MGUS is characterized by the presence of a constant serum level of monoclonal paraprotein (less than 3 g/dl) termed “M-spike” as detected by a persistent band in the gamma region of a serum protein electrophoresis (SPEP, **Figure 1.4a**) in the absence of end-organ damage. While largely benign, MGUS is associated with increased fracture risk and osteoporosis (Melton et al., 2005), and MGUS patients have elevated serum levels of OC-activating (MIP1 α) and OB-inhibiting (DKK1) factors (Ng et al., 2011). Importantly, MGUS is the requisite precursor to multiple myeloma (MM), and progresses to overt malignancy at a rate of 1% per year. Due to the largely asymptomatic state and low rate of transformation to myeloma (lifetime risk of 10-30% (Kyle et al., 2010; Sirohi and Powles, 2006; Zingone and Kuehl, 2011)), MGUS is not clinically treated, though patients are monitored with annual blood chemistry tests.

Step-wise transformation from MGUS multiple myeloma

MM is the second most common hematological malignancy and is invariably fatal with a ~6 year median survival (Kumar et al., 2013). MM is a malignancy of plasma B-cells that is clinically diagnosed by an M-spike of >3 g/dL and the presence of CRAB syndromes: hypercalcemia, renal insufficiency, anemia, and lytic bone lesions, highlighting its dependence on the bone microenvironment (**Figure 1.4b**).

Normal plasma B-cell development results in a long-lived non-proliferative antibody-producing cell. One of the hallmarks of B-cell differentiation is a DNA rearrangement for increased variation: VDJ recombination in immunoglobulin (Ig) heavy and light chains, somatic hypermutation, and Ig heavy chain switch recombination. In the bone marrow, pro- and pre-B-cells undergo Ig heavy and light chain recombination, respectively. Immature B-cells that undergo receptor editing and express IgM receptor leave the bone marrow and travel to the spleen or lymph nodes as antigen-presenting cells. Upon encountering an antigen, the B-cell will endocytose the antigen and presents the antigenic peptides as part of the MHC II complex. These activated B-cells enter a germinal center and undergo somatic hypermutation of both the heavy and light chains. Cells that express high-binding antigen-receptors undergo Ig class switch recombination then home to the bone marrow as mature, antibody producing plasma B-cells.

The affected cell in MGUS and MM is the typically non-proliferative terminally-differentiated post-germinal center B-cell. In MGUS, there is a clonal expansion of one or more of these plasma cells, resulting in an elevated level of immunoglobulin in the serum. MM is characterized by a further expansion of one or more of these clones to fill the marrow space, again resulting in an elevated immunoglobulin level, but now accompanied with more significant end-organ damage.

The bone microenvironment contributes to MGUS and MM pathology

Differentiation and function of normal plasma cells is dependent on the bone marrow microenvironment. Bone marrow stromal cells and OBs support B-cell lymphopoiesis, proliferation, and plasma cell homing to the marrow. Likewise, MM::microenvironment

interactions parallel normal B-cell::microenvironment cross-talk, with similar mechanisms identified for homing (CXCR4/SDF1 gradient) and proliferation (IL-6, IGF1, TGFB) (reviewed in (Kuehl and Bergsagel, 2002)). In addition, myelomas further modulate the bone microenvironment and produce OC-stimulatory (Basak et al., 2009; Esteve and Roodman, 2007; Oyajobi et al., 2003) and OB-inhibitory factors (Giuliani et al., 2005; Yaccoby, 2010) that deregulate the coupled process of healthy bone remodeling (Mundy, 2002; Weilbaecher et al., 2011). This results in osteolytic lesions in 70-80% of MM patients (Terpos et al., 2007) (**Figure 1.4b**). Such pathologic bone resorption releases tumor growth factors stored within the bone matrix. Bone marrow stromal cells, a heterogeneous population including mesenchymal stem cells, support myeloma growth through adhesion-dependent mechanisms (VLA-4/VCAM) and the production of soluble growth factors including IL-6(Terpos et al., 2007). MM causes significant bone destruction, hypercalcaemia, bone pain, and fracture.

Tumor associated macrophages promote myeloma progression

In addition to the crucial role of bone remodeling cells, there is a growing literature implicating tumor-associated macrophages (TAMs) in the pathogenesis of MM (reviewed in (Asimakopoulos et al., 2013; Berardi et al., 2013; Ribatti et al., 2013)). TAMs are typically categorized as classically-activated pro-inflammatory macrophages (M1) or alternatively-activated anti-inflammatory macrophages (M2), though the distinction between the two classes likely represents a spectrum rather than specific identity. M1 macrophages, activated by bacterial lipopolysaccharide (LPS) and interferon-gamma (IFN γ), promote a strong host immune response. In contrast, M2 macrophages, activated by IL-4, IL-13, and TGF β , suppresses Th1-mediated inflammation and promotes wound healing, including angiogenesis and destruction of

the extracellular matrix. Thus, even within their normal physiologic roles, M1 macrophages are inherently anti-tumor while M2 macrophages promote tumor progression.

MM patients with active disease have higher percentage of macrophages in the bone marrow than either MGUS patients or patients with non-active disease (Scavelli et al., 2008). In addition, these macrophages are functionally distinct from non-affected patients and contribute to angiogenesis through vasculogenic mimicry (Scavelli et al., 2008). MM TAMs have increased pro-MM factor secretion such as IL-6 (Kim et al., 2012; Zheng et al., 2009) and higher levels of pro-angiogenic VEGF expression compared to non-MM macrophages (Ribatti et al., 2006; Scavelli et al., 2008; Vacca and Ribatti, 2011). The role of *Samsn1* in macrophages will be explored in **Chapter 3**.

Genetic risk factors contributing to MGUS and MM susceptibility

Human population studies suggest that genetic risk factors underlie susceptibility to MGUS and MM. Interestingly, however, the majority of plasma-cell intrinsic genetic events in MM cells are present in MGUS-affected B-cells (Davies et al., 2003), though not in normal plasma B-cells. Epidemiological studies have identified a higher incidence for MM in African Americans and that this is the result of elevated risk to MGUS, rather than an increased rate of conversion from MGUS to MM (Kyle et al., 2010; Kyle et al., 2006; Landgren et al., 2006). In addition, studies in affected families showed a higher risk of MM in patients with an MGUS-affected relative (Jain et al., 2009; Kyle et al., 2004; Vachon et al., 2009).

Genome wide significance studies of MM have identified seven SNPs that confer a significant increase in MM risk (Broderick et al., 2012; Chubb et al., 2013). Interestingly, a recent study in an MGUS patient population showed that these SNPs also conferred increased

risk to MGUS (Weinhold et al., 2014), providing further evidence that increased MM risk is due to increased MGUS risk. These studies highlight the need for a better understanding of the genetic predisposition to MGUS that will be the subject of **Chapter 3**.

C57Bl/KaLwRij is a spontaneous mouse model of MGUS and MM

One of the most common experimental models for MGUS and MM is the C57BL/KaLwRij mouse (KaLwRij). KaLwRij was first identified to have a high frequency of benign idiopathic paraproteinaemia (BIP), the murine counterpoint to human MGUS, in 1974 (Radl and Hollander, 1974). KaLwRij mice have increased serum levels of homogeneous immunoglobulin by SPEP, similar to the M-spike observed in MGUS and MM patients, by 12 months of age with a penetrance of ~45% (Radl et al., 1978). Affected mice progress to overt malignancy at a rate of approximately 1% with similar clinical features as human MM, including severe bone pathology (Radl et al., 1978).

5T myeloma cell lines were generated from spontaneous myelomas in KaLwRij mice, and can be transplanted into KaLwRij mice to propagate the myeloma (Alici et al., 2004; Asosingh et al., 2000; Vanderkerken et al., 2003). Intravenous injection into KaLwRij mice yields robust bone marrow-disseminated myeloma with significant osteolytic bone lesions and increased monoclonal paraprotein (M-spike) within 28 days (Dallas et al., 1999; Edwards et al., 2009; Garrett et al., 1997). Importantly, the 5TMM cell lines will not engraft in the closely related C57Bl/6 (B6) strain (Asosingh et al., 2000), highlighting the requirement of a supportive host microenvironment for establishment of early disease. Notably, while KaLwRij represents an ideal model for MGUS and for a MM-supportive host microenvironment, the genetic basis of

BIP susceptibility in these mice remains largely unknown. We characterized the genetic variation between KaLwRij and B6 using SNP mapping which is presented in **Chapter 3**.

Mouse genetic mapping to identify genetic susceptibility loci for BIP

The KaLwRij mouse strain is an ideal model to dissect genetic risk loci contributing to the complex trait of BIP susceptibility, analogous to human MGUS. Importantly, identifying germline risk alleles will encompass genes at play in all cell types participating in the step-wise progression from a normal plasma cell to overt MM, including host stromal cells predicted to contribute to MGUS and MM. In our studies presented in **Chapter 3** we use a variety of genetic techniques to identify MGUS risk alleles using KaLwRij mice and human MM samples.

The BIP-prone KaLwRij strain has been interbred since approximately 1978, and we demonstrated that it is distinct from, but closely related to, the commonly used wild type (and BIP-resistant) strain, B6 (**Chapter 3, Figure 3.1**). We used SNP analysis, also known as linkage disequilibrium mapping, to identify candidate loci underlying risk to MGUS. Haplotype analysis, while uncommon in the genomic era, is used to narrow quantitative trait loci regions and to characterize regions of interest contributing to phenotype in recombinant inbred strain analysis (Burgess-Herbert et al., 2008).

Linkage disequilibrium is the non-random assortment of alleles based on physical proximity. Loci that are physically proximal to each other are more likely to be inherited together than expected by random assortment, due to low rates of recombination in short physical space. Contiguous loci that are inherited together represent a haplotype. Therefore, by identifying regions which are shared in “high” phenotype mouse strains and not in “low” phenotype mouse strains allows for the identification of candidate gene loci. Traditional

haplotype block analysis assumes that any variation between strains is a result of ancestral variation rather than recent variation, resulting in large DNA regions that are identical by descent. We modified the approach to identify smaller units of variation between the closely related KaLwRij and B6, and therefore used a lower threshold than is typical for this analysis.

In our analyses presented in **Chapter 3**, we identified candidate lists of genes underlying susceptibility to (1) murine BIP, (2) human MM/MGUS, and (3) both murine BIP and human MM/MGUS.

Goals of the present study

Epidemiological evidence points to genetic risk to MGUS and subsequent progression to MM, representing a “congenial soil” for malignant cell transformation, both inherent to the pre-malignant B-cell and to the non-cancerous host cells contributing to disease progression.

In **Chapter 3**, we focus on whole-host “congeniality” to MGUS and MM. We identify genetic risk loci contributing to susceptibility to microenvironment-dependent MGUS. Using a combinatorial approach, we compiled candidate gene lists derived from mouse SNP analysis and human MM patient association studies to ultimately identify a shared candidate list of five genes and focused our studies on *Samsn1*. We show that the most common murine model for human MGUS and myeloma, KaLwRij mouse strain, has a germline deletion for the B-cell inhibitor *Samsn1*. We present compelling evidence that *Samsn1* confers genetic risk to B-cell malignancy through effects both in pre-malignant cells and cooperating cells of the host microenvironment, namely TAMs. Therefore, *Samsn1* represents a single tumor-suppressor gene contributing to myeloma progression through two mutually exclusive mechanisms.

Figure 1.1. The “vicious cycle” of bone metastasis.

In the bone marrow space, metastatic cells secrete factors (including PTHrP, IL-6, VEGF, TNF, and MMPs) to stimulate bone resorption, through both direct and indirect effects on osteoclasts. In turn, osteoclasts release bone-sequestered growth actors (including TGFβ and IGFs) that further stimulate tumor growth.

Reproduced from (Weilbaeher et al., 2011).

Integrin Expression During Bone Metastasis

Figure 1.2.

Expression of integrins in tumor cells and host microenvironment cells during metastasis. Reproduced from (Schneider et al., 2011).

Figure 1.3. Nitric oxide (NO) exerts a biphasic (or “Goldilocks”) effect on cell activation. In the absence of nitric oxide, cells remain inactive or fail to differentiate. Under tonic levels of NO, synthesized by the constitutive nitric oxide synthases (NOSs) endothelial NOS and neuronal NOS, cells are activated or differentiate. High levels of NO, produced by inducible NOS, results in cell toxicity.

Figure 1.4. Clinical diagnosis of MGUS and multiple myeloma.

(a) Serum protein electrophoresis (SPEP). Arrowhead indicates band in the gamma region, indicative of an accumulation of monoclonal paraprotein (M-spike). Negative (left) and positive (right) M-spike.

(b) X-ray of a multiple myeloma patient with characteristic “hole-punch” bone lesions (arrows). Reproduced from the American Academy of Orthopedic Surgeons.

Table 1.1. Integrin $\beta 3^{-/-}$, CD47 $^{-/-}$, and TSP1 $^{-/-}$ mouse model phenotypic overlap

Mouse model	Primary tumor		Bone metastasis		Homeostatic bone	
	Tumor	Angiogenesis	Tumor	Osteolysis	Bone volume	Osteoclasts
$\beta 3^{-/-}$	↑	↑	↓	↓	↑	↓
CD47 $^{-/-}$	↓	---	↓	↓	↑	↓
TSP1 $^{-/-}$	↑	↑	?	?	?	?

Chapter 2

Thrombospondin-1 regulates bone homeostasis through effects on bone matrix integrity and nitric oxide signaling in osteoclasts

Abstract

Thrombospondin-1 (TSP1), an endogenous antiangiogenic, is a widely expressed secreted ligand with roles in migration, adhesion and proliferation and is a target for new therapeutics. While TSP1 is present in the bone matrix and several TSP1 receptors play roles in bone biology, the role of TSP1 in bone remodeling has not been fully elucidated. Bone turnover is characterized by coordinated activity of bone-forming osteoblasts (OB) and bone-resorbing osteoclasts (OC). TSP1^{-/-} mice had increased bone mass and increased cortical bone size and thickness compared to wild type (WT). However, despite increased size, TSP1^{-/-} femurs showed less resistance to bending than expected, indicative of diminished bone quality and a bone material defect. Additionally, we found that TSP1 deficiency resulted in decreased OC activity in vivo and reduced OC differentiation. TSP1 was critical during early osteoclastogenesis, and TSP1 deficiency resulted in a substantial overexpression of inducible nitric oxide synthase (iNOS). Importantly, administration of a NOS inhibitor rescued the OC functional defects of TSP1^{-/-} mice in vivo. To investigate the role of bone-derived TSP1 in osteoclastogenesis, we found that wild type (WT) pre-OCs had defective iNOS expression when cultured on TSP1^{-/-} bone compared to WT bone, suggesting that TSP1 in bone plays a critical role in iNOS signaling during OC development. These data implicate a new role for TSP1 in bone homeostasis with roles in maintaining bone matrix integrity and regulating OC formation. It will be critical to monitor bone health of patients administered TSP1-pathway directed therapeutics in clinical use and under development.

Introduction

Bone is a dynamic tissue, characterized by balanced bone resorption and formation. This bone remodeling is necessary to preserve the structural integrity of the skeleton and to maintain calcium and phosphate homeostasis (Baron, 1996; Hadjidakis and Androulakis, 2006). Bone is a matrix composed of two compartments: osteoid (primarily collagen type I fibers) and mineral (calcium-phosphate hydroxyapatite crystals). The bone matrix also contains numerous noncollagenous proteins including growth factors, proteoglycans, and adhesion molecules. These molecules contribute to maintenance of homeostatic bone remodeling, promoting cell attachment, differentiation, and growth of bone remodeling cells. In addition, some molecules aid in osteoid and mineral matrix organization, directly influencing bone strength.

Mesenchymal osteoblasts (OBs) form bone by depositing collagen and other molecules to form osteoid and subsequently calcify this matrix to form rigid bone. Osteoclasts (OCs), polarized multi-nucleated hematopoietic cells formed from the fusion of macrophages, resorb bone through protease- and acid-dependent processes. The formation and activity of OCs and OBs is a tightly coupled process. OCs are activated by OB-derived cytokines such as M-CSF and RANK-L. In turn, OCs promote osteoblastic bone formation by releasing stored growth factors including bone morphogenic proteins, TGF β , and insulin growth factor from the bone matrix. Misregulation of healthy bone remodeling, as in cancer metastasis, arthritis, or osteoporosis, leads to decreased bone integrity, pathologic fracture, nerve-compression syndromes, and hypercalcemia (Weilbaecher et al., 2011). While many factors that individually regulate OC and OB formation and activity have been identified, our understanding of the role of OB-deposited bone matrix-sequestered proteins in homeostatic OC activity remains incomplete.

Thrombospondin-1 (TSP1) is a large secreted protein that binds at least 11 distinct receptors, including β 3 integrin, CD47, and CD36, thereby influencing downstream pathways. By regulating migration, adhesion and proliferation, TSP1 participates in diverse processes including angiogenesis, inflammation, and wound healing. TSP1 was the first identified endogenous antiangiogenic molecule, and TSP1 mimetics have entered clinical trials as cancer therapeutics (Taraboletti et al., 2010). Antibodies against the TSP1 receptor CD47, used to induce macrophage phagocytosis of cancer cells, have completed pre-clinical studies (Tseng et al., 2013; Weiskopf et al., 2013), and a humanized antibody is under clinical development. In addition, nitric oxide (NO) signaling, a pathway regulated by TSP1, is being therapeutically targeted for vasodilation (NO donors) or hypotension (NO synthase inhibitors) (Deshpande et al., 2012). As these TSP1 pathway-targeted therapies enter broad clinical use, it is important to consider the action of TSP1 in other systems, including the skeleton, where TSP1 receptors CD47, β 3 integrin, and CD36 (Faccio et al., 2003b; Kevorkova et al., 2013; Koskinen et al., 2013; McHugh et al., 2000; Schneider et al., 2011; Uluckan et al., 2009) are involved in OC and OB signaling. Bone-related off-target effects will be especially crucial to consider in advanced cancer patients at risk for skeletal metastasis and post-menopausal women who are at risk for osteoporosis.

TSP1 deficient mice are reported to have mild spine deformation (Crawford et al., 1998) and mild growth plate cartilage disorganization (Posey et al., 2008) in addition to enhanced angiogenesis (Smadja et al., 2011) but detailed analysis of bone has not been reported. TSP1 is expressed by OBs and is present in osteoid and mineralized bone matrix (Grzesik and Robey, 1994; Kannus et al., 1998; Robey et al., 1989) where it is directly deposited by bone-forming OBs (Cleazardin et al., 1989; Robey et al., 1989). TSP1 is involved in OB differentiation in part

through activation of latent TGF- β (Bailey Dubose et al., 2012; Ueno et al., 2006), and TSP1 receptors CD47 and CD36 also regulate OB (Kevorkova et al., 2013; Koskinen et al., 2013). TSP1 is a regulator of nitric oxide (NO) in endothelial cells, platelets, and vascular smooth muscle cells (Chen et al., 2000; Isenberg et al., 2009), but only receptors CD36 and CD47 have been implicated in NO regulation (Isenberg et al., 2009; Isenberg et al., 2006; Isenberg et al., 2005). TSP1 has been implicated in OC activity, but its mechanism of action remains unknown (Carron et al., 1995). TSP1-CD47 interactions play a role in the formation of multiple myeloma-dendritic cell fusions with bone-resorbing capacity (Kukreja et al., 2009), and TSP1-CD36 ligation can promote osteoclastic resorption on dentine slices (Carron et al., 2000). CD47^{-/-} mice have a bone resorption defect (Koskinen et al., 2013; Lundberg et al., 2007; Uluckan et al., 2009), which we have shown is due to increased iNOS in OCs (Uluckan et al., 2009). Together these data led us to hypothesize that OB-secreted TSP1 sequestered in bone matrix will modulate OC function thereby coupling OB activity to OC formation.

In this study, we describe the role of bone-sequestered TSP1 in the maintenance of bone homeostasis, both as a structural protein contributing to bone strength and as a signaling ligand promoting OC formation. Here we have used mice genetically deficient in TSP1 and neutralizing anti-TSP1 antibody to investigate the role of TSP1 in bone homeostasis. Together, these data implicate a novel role for TSP1 in bone homeostasis, both in mediating bone matrix integrity and by regulating OC formation as a matrix-derived paracrine signaling molecule. Our findings provide an important rationale to monitor the effects on bone health of TSP1 pathway-directed therapeutics, currently in clinical use and under development, especially in patients affected by bone pathology such as osteoporosis and skeletal metastasis.

Materials and Methods

Animals

TSP1^{-/-} mice were originally obtained from Jack Lawler (Lawler et al., 1998) and backcrossed over 20 times to C57BL/6J. TSP1^{-/-} and TSP1^{+/+} mice were housed in shared pathogen-free conditions according to the guidelines of the Division of Comparative Medicine, Washington University School of Medicine. The animal ethics committee approved all experiments.

Reagents

Anti-TSP1 function blocking antibody, clone A4.1 (IgM, mouse anti-human)(Annis et al., 2006) was purchased from Thermo Scientific (Waltham, MA). TSP1 is highly conserved among species and clone A4.1 has cross-species reactivity with mouse and bovine TSP1. IgM isotype control was purchased from eBioscience (San Diego, CA).

Micro-computed tomography

Tibiae and femurs from TSP1^{-/-} and WT sex-matched mice were suspended in agarose and tibial metaphyses and femoral mid-diaphysis were scanned by micro-computed tomography (uCT-40; Scanco Medical) as described previously (Heller et al., 2012; Uluckan et al., 2009). For image acquisition, the long bones were placed in a 13-mm holder and scanned. The cancellous region was selected using contours inside the cortical shell on each 2d image. The growth plate was used as a marker to determine a consistent location to start analysis and 40 slices were analyzed. A 3-dimensional cubical voxel model of bone was built and calculations made: relative trabecular bone volume over total volume, trabecular number, and trabecular spacing. The cortical region was selected using contours outside the cortical shell at the mid-diaphysis and 50 slices were analyzed. The average cross-sectional geometry measurements were calculated for

cortical thickness and total cross-sectional area. The bending moment of inertia was determined using standard engineering parallel-axis theory as previously described (Brodt et al., 1999; Silva et al., 2006).

Bone biomechanics

Immediately following dissection, femurs were frozen at -20°C for a minimum of 12 hours.

Femurs were thawed in phosphate-buffered saline for 1 h prior to use, and testing was carried out at room temperature using a servohydraulic testing machine (8841 Dynamite, Instron, Norwood, MA). Femurs were positioned on two supports 7 mm apart, and the central loading point was the mid-diaphysis. Displacement was applied transverse to the long axis of the bone at a rate of 0.03 mm/s until failure. Force-displacement data were recorded at 60 Hz and analyzed to determine stiffness (a measure of elastic resistance to bending), yield force (a measure of the force required to permanently deform the bone), ultimate force (the highest force attained prior to failure), post-yield displacement (a measure of ductility) and energy-to-fracture (a measure of overall resistance to fracture) (Brodt et al., 1999; Silva et al., 2006). Estimated material properties (elastic modulus, yield stress, ultimate stress) were calculated using standard engineering beam theory that normalizes for bone size.

Reference point indentation

Femurs were subjected to reference point indentation as previously described (Randall et al., 2009). A 25 μm testing probe was placed on the cortical bone surface and a preload force of 0.1N and a waveform of 10 cycles of 2N force was applied as a frequency of 2 Hz (Biodent, Active Life Sciences, Santa Barbara, CA). Each bone was subjected to 3 indents 1 mm apart. Measurements were made for each indent: initial indentation distance and indentation distance increase (cycle 1 – cycle 10).

Serum CTX assay

Carboxy-terminal telopeptide collagen crosslinks (CTX) was measured in the serum of overnight fasted mice by ELISA (RatLaps; Immunodiagnostic Systems, Scottsdale, AZ) according to the manufacturer's instructions.

Serum P1NP assay

N-terminal propeptide of type I procollagen (P1NP) was measured in serum of overnight fasted mice using ELISA (Immunodiagnostic Systems, Scottsdale, AZ) according to the manufacturer's instructions.

L-NAME administration

L-NAME (Sigma Aldrich, St. Louis, MO) was administered in the drinking water of 8 week old mice for 6 weeks, changed every 2 days (40 mg/kg/day).

In vitro osteoclast differentiation

To generate macrophages, whole bone marrow cells were cultured in α MEM, 10% FBS, 1% penicillin-streptomycin, 100 ng/ml MCSF for 3 days as previously described (Morgan et al., 2010). To generate OCs, 9×10^4 /ml were plated on plastic or bone powder as indicated and cultured in α MEM, 10% FBS (on plastic), 1% penicillin-streptomycin, 50 ng/ml MCSF, 50 ng/ml RANKL, refed every 48 hours. Where indicated, macrophages were cultured with 5 μ g/ml antibody. TRAP staining was performed according to the manufacturer's instructions (Sigma-Aldrich, St. Louis, MO).

In vitro osteoblast differentiation

To generate bone marrow stromal cells (BMSCs), whole bone marrow cells were cultured in ascorbic-acid free α MEM, 10% FBS, 1% penicillin-streptomycin for 7 days. For OB differentiation, 2×10^5 BMSC/ml were cultured in α MEM, 10% FBS, 1% penicillin-streptomycin,

10 mM β -glycerophosphate, 50 ug/ml ascorbic acid for 14 days, refed every 7 days. Cultures were fixed in 10% neutral buffered formalin and stained with Alkaline Phosphatase (Fast Blue RR salt, Sigma Aldrich) and 0.4% Alizarin Red. Chromogenic alkaline phosphatase was quantitated according to manufacturer's instructions (Sigma-Aldrich, St. Louis, MO). Alizarin red stain was measured using the Osteogenesis Quantitation Kit according to manufacturer's instructions (Millipore, Billerica, MA).

Bone powder coated plates

Plates were coated with bone powder as previously described (Cremasco et al., 2012) with modifications. Bone marrow was flushed from the long bones of WT and TSP1^{-/-} mice, and the bones were frozen at -20°C. Frozen bones were crushed to powder using a Bullet Blender Bead Lysis Kit (Midsci, St. Louis, MO), and the powder was washed 3 times in 70% ethanol. Plates were coated with 1:20 bone powder:PBS + 4 ug/ml poly-l-lysine for 4 hours at 68°C. Plates were sterilized under UV light and experiments completed as described.

Quantitative reverse-transcription PCR

RNA was extracted using RNeasy Mini kit (Qiagen, Venlo, Netherlands) and cDNA generated using iScript (Bio-Rad, Hercules, CA). Quantitative PCR was completed using SsoFast EVA Green Supermix (Bio-Rad, Hercules, CA).

qRT-PCR primer sequences (forward/reverse)

NFATc1:

GGTAACTCTGTCTTTCTAACCTTAAGC / GTGATGACCCCAGCATGCACCAGTCA

DC-STAMP: ACAAACAGTTCCAAAGCTTGC / TCCTTGGGTTTCCTTGCTTC

TRAP: CAGCTGTCCTGGCTCAAAA / ACATAGCCCACACCGTTCTC

β 3 integrin: TGGTGCTCAGATGAGACTTTGTC / GACTCTGGAGCACAATTGTCCTT

Cathepsin K: GAGGGCCAACTCAAGAAGAA / GCCGTGGCGTTATACATACA

iNOS: GGCAGCCTGTGAGACCTTTG / GCATTGGAAGTGAAGCGTTTC

cyclophilin: AGCATACAGGTCCTGGCATC / TTCACCTTCCCAAAGACCAC

In vivo calcein labeling

Calcein labeling was completed as previously described (Su et al., 2012). Briefly, mice were injected 8 and 2 days prior to sacrifice with 20 mg/kg calcein (Sigma-Aldrich, St. Louis, MO) in a 2% sodium bicarbonate solution i.p. Calveria were fixed in 70% ethanol and embedded in methylmethacrylate and sectioned.

Bone histomorphometry

Bones were prepared and analyzed as previously described. Mouse tibiae were fixed in 10% formalin for 24 hours and decalcified in 14% EDTA solution for 2 weeks. Paraffin embedded sections were stained with TRAP. Sections were analyzed by a blinded operator according to standard protocol using Bioquant Osteo V7 10.10 (Bioquant Image Analysis Corp.).

Statistical analysis

All experiments were analyzed using Student's t-test. In calculating two-tailed significance levels for equality of means, equal variances were assumed for both populations. Results were considered to reach significance at $p < 0.05$. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$.

Results

TSP1^{-/-} mice had increased cancellous and cortical bone mass

We have previously shown that mice deficient in the TSP1-receptor CD47 have modestly increased bone mass (Koskinen et al., 2013; Lundberg et al., 2007; Uluckan et al., 2009). To determine if TSP1^{-/-} mice would similarly display increased bone volume, we performed microCT analysis on WT and TSP1^{-/-} mice to evaluate cancellous and cortical bone. We observed a significant increase in trabecular bone volume in 8 week-old (+32.6%), 16 week-old (+112.1%), and 32 week old (+158.8%) TSP1^{-/-} mice (**Figure 2.1 A-B**). Coordinately, trabecular number was increased and trabecular spacing was decreased in TSP1^{-/-} mice (**Figure 2.2**). This dramatic increase in trabecular bone volume is in contrast to the modest bone volume phenotypes of TSP1-receptor deficient mice (CD47, CD36, $\beta 3$ integrin^{-/-} (Faccio et al., 2003a; Kevorkova et al., 2013; Koskinen et al., 2013; McHugh et al., 2000; Uluckan et al., 2009)), and is consistent with TSP1 binding to multiple receptors. TSP1^{-/-} mice also had significantly increased cortical bone thickness and total cortical area at 12 weeks (**Figure 2.1 C-E**), indicating a geometrically larger bone in TSP1^{-/-} compared to WT mice. Therefore, TSP1^{-/-} mice had both increased size and increased relative bone mass compared to WT mice.

TSP1 improved bone strength through effects on the bone material properties

Because TSP1 null mice showed enhanced cortical thickness and cross-sectional area (**Figure 2.1 C-E**), and because TSP1 is a known component of the bone matrix (Cleazardin et al., 1989; Robey et al., 1989), we hypothesized that TSP1 deletion may influence bone mechanical

properties. Bone mechanical properties are influenced by many factors including overall structural morphology and the material properties (“quality”) of the bone matrix.

MicroCT analysis of the femoral mid-diaphysis showed a striking increase in moment of inertia in TSP1^{-/-} mice (+67.1%), predicting increased strength based on morphology (**Figure 2.3 A**). Interestingly, however, direct measurement of mechanical strength by 3-point bending did not recapitulate these results. Bone is permanently deformed upon reaching its yield force and eventually fractures after reaching its highest (ultimate) force. TSP1^{-/-} femurs showed only a modest increase ultimate force (+16.7%) and no difference compared to WT in yield force (**Figure 2.3 B-C**). Notably, a normalized measure of yield force that accounts for differences in morphology (yield stress) is significantly decreased in TSP1^{-/-} femurs (**Figure 2.3 D**). This suggests a bone material defect in TSP1^{-/-} mice that offsets the morphological size advantage.

To directly evaluate the local material properties of the bone matrix, we performed reference point indentation by applying a repetitive force on the cortical bone surface through a small probe. TSP1^{-/-} femurs had increased initial indentation distance and a larger increase in indentation at the end of 10 cycles (**Figure 2.3 E-F**). These data indicate that TSP1^{-/-} bone material had less resistance to microfracture compared to WT control. Dynamic histomorphometric analysis to quantitate bone formation rate and mineral apposition rates were difficult to perform because of fuzzy and poor bone mineral labeling in the TSP1^{-/-} mice (**Figure 2.4 B**), consistent with a bone mineral defect. Taken together, these mechanical and material properties demonstrate that TSP1 plays a role in maintaining the matrix quality necessary for normal bone strength.

TSP1^{-/-} mice had decreased bone resorption and OC formation

While we identified differences in long bone size and bone material properties that contribute to reduced bone quality, the underlying mechanism leading to the increased bone mass in TSP1^{-/-} mice remained unclear. The progressive increase in trabecular bone volume with age in TSP1 null animals (**Figure 2.1 A-B**) is consistent with a failure in bone resorption. To test this, we measured serum markers of bone turnover, which include CTX (carboxy-terminal telopeptide collagen crosslinks), a measure of osteoclastic bone resorption and P1NP (pro-collagen type I N-terminal telopeptide), a measure of OB function. There were no statistically significant differences in serum P1NP at 8, 16, or 32 weeks of age (**Figure 2.4 A**) and no differences in ex vivo OB formation assays (**Figure 2.4 C-E**). We did observe significant decreases in serum CTX levels in TSP1^{-/-} mice compared to WT controls at 8 weeks and 16 weeks of age (**Figure 2.5 A**) consistent with a defect in OC resorption. Histomorphometric analysis of mouse tibiae showed that TSP1^{-/-} mice did not have significantly different OC number/bone surface at 8 or 32 weeks of age (**Figure 2.6**). To investigate the role of TSP1 in osteoclastogenesis and function, we differentiated WT primary OCs from bone marrow macrophages in vitro. TSP1 is secreted by activated platelets, leading to high levels of the protein in blood serum. Fetal bovine serum (FBS), necessary in OC culture media, contains approximately 100 ng/ml TSP1 (data not shown). To neutralize FBS-derived TSP1, we treated cultures with TSP1 neutralizing antibody (clone A4.1). Notably, in control cultures, TSP1^{-/-} OCs were indistinguishable from WT OCs, indicating that exogenous, FBS-derived TSP1 was sufficient to maintain normal OC formation (**Figure 2.7**). In contrast, OC differentiation in the presence of anti-TSP1 antibody was dramatically reduced, while cells treated with the IgM control antibody developed large multinucleated TRAP⁺ OCs (**Figure 2.5 B, left panels; Figure**

2.7). Interestingly, while there was no change in NFATc1, a marker of OC lineage commitment, RT-qPCR analysis showed decreased expression of OC differentiation markers (DC-STAMP, TRAP, β 3 integrin, Cathepsin K) in anti-TSP1 antibody treated cultures, consistent with reduced osteoclastogenesis (**Figure 2.5 C**).

To define the temporal requirement of TSP1 in OC formation, we treated early (d0-2), mid (d3-4), or late (d4-5) stage OC cultures with A4.1 to neutralize TSP1 at different times during OC formation. We found that neutralizing TSP1 in early OC precursors (d0-2) was sufficient to decrease OC differentiation, while mid- or late-stage TSP1 neutralization had no effect (**Figure 2.5 B**). These data indicate that TSP1 promotes early-stage OC formation while it is dispensable for later maturation.

Inhibition of NOS rescued TSP1^{-/-} bone resorption phenotype

TSP1 is an established mediator of NO signaling in endothelium and inflammatory macrophages (Chen et al., 2000; Isenberg et al., 2009), and we have previously shown that TSP1-receptor CD47 null mice show reduced OC formation due to increased levels of iNOS transcription (Uluckan et al., 2009). In primary OC cultures treated with TSP1 neutralizing antibody, we saw a dramatic elevation of iNOS expression compared to isotype control (**Figure 2.8 A**). Neither nNOS nor eNOS were elevated in anti-TSP1 antibody treated cultures (data not shown). To test whether the bone resorption defect in TSP1^{-/-} mice was attributable to elevated NO signaling, we inhibited NO production in vivo by administration of the pan-NOS inhibitor L-NAME in the drinking water of TSP1^{-/-} and WT mice (40 mg/kg/day) for six weeks. L-NAME-treatment increased the serum CTX level of TSP1^{-/-} mice to that of their WT counterparts, demonstrating that osteoclastic bone resorption was restored (**Figure 2.8 B**). Together, these data

indicate that aberrant NO signaling in TSP1^{-/-} mice was in part responsible for decreased OC function in vitro and in vivo.

TSP1 in bone was sufficient to inhibit OC iNOS

It is well established that TSP1 is secreted by OBs and is present in the bone matrix (Cleazardin et al., 1989; Robey et al., 1989). We found that TSP1 contributes to maintaining bone strength (**Figure 2.3**), but its role as matricellular signaling molecule in the bone remained unknown.

We hypothesized that bone-sequestered TSP1 signals to immature OCs to inhibit RANK-L-induced iNOS. We therefore differentiated WT bone marrow macrophages into OC on plates coated with bone powder derived from WT or TSP1^{-/-} mice. The osteoclastogenic culture medium was serum free to ensure that the bone was the only source of TSP1. OCs plated on TSP1^{-/-} bone powder had increased iNOS expression compared to the same cells plated on WT bone after 24 hours of differentiation (**Figure 2.9 A**). Notably, the lineage marker NFATc1 was unchanged between cells plated on WT and TSP1^{-/-} bone, indicating that osteoclastogenic signaling was initiated equally (**Figure 2.9 A**). Together, these data indicate that bone-sequestered TSP1 plays a critical role in iNOS signaling during early osteoclastogenesis.

Discussion

We demonstrate here that TSP1 is critical for the maintenance of bone homeostasis, contributing both to matrix material integrity and regulation of OC formation (**Figure 2.9 B**). TSP1^{-/-} mice were protected from age-associated bone loss and had increased cross-sectional area, but failed to show proportional resistance to bending. Instead, we found that TSP1 null mice had a bone material properties defect, resulting in decreased bone material quality and reduced strength. The increased trabecular bone mass in TSP1^{-/-} mice was due to decreased osteoclastic resorption that was rescued upon in vivo pharmacologic inhibition of NO signaling. We demonstrated that TSP1 inhibition of iNOS was necessary for early OC formation, but was dispensable for later OC maturation. Finally, we showed that bone-sequestered TSP1 modulated OC iNOS levels, indicating TSP1 as a novel paracrine signaling molecule, coupling OB function to OC formation.

The bone matrix is composed of two compartments: mineral of calcium-phosphate hydroxyapatite crystals and osteoid of collagen (90%) and other non-collagenous proteins (10%, NCP). Many diseases including osteogenesis imperfecta and rickets impact bone quality through modification of the osteoid tissue or mineralized matrix leading to increased risk of fragility fracture. Notably, TSP1 binds many components of the bone matrix, including collagen and hydroxyapatite, as well as numerous NCPs including osteonectin, fibronectin, osteopontin, and proteoglycans, among others (reviewed in (Tan and Lawler, 2009)). These NCPs are critical for bone matrix organization, both for collagen organization and hydroxyapatite deposition (Terminie and Robey, 1996). In osteogenesis imperfecta patient OBs, secretion of TSP1 and its NCP binding partners are misregulated, suggesting that TSP1 participates with collagen and other

NCPs for osteoid organization (Fedarko et al., 1995). Our data indicate that TSP1 is critical for maintaining the material properties of bone necessary for high bone quality. We postulate that TSP1 mediates the proper physical organization and protein stoichiometry of the bone matrix through its interactions with other bone matrix components. Further work is necessary to understand the role of the matrix proteins that interact with TSP1 to mediate bone quality.

The TSP1^{-/-} bones had both cancellous and cortical bone phenotypes. The increased area and cortical thickness of the TSP1^{-/-} bones suggest an effect of TSP1 loss on OB bone formation. Assessment of bone formation rate and mineral apposition rates by dynamic histomorphometry in the TSP1^{-/-} mice were hampered by the lack of double labels and diffuse single labels (**Figure 2.4 B**). These labeling abnormalities are consistent with a bone matrix defect. Ex vivo OB formation assays were not abnormal in the TSP1^{-/-} cells or in WT cells in the presence of TSP1 neutralizing antibody (data not shown). It is possible that there was a compensatory increase in bone mineral formation due to defects in bone quality or that there are effects of TSP1 on osteocyte and OB formation and function that may be present early in development. Experiments are underway to explore the role of TSP1 in OBs.

In addition to its role in maintaining bone matrix material integrity, we also found that TSP1 binding to early OC precursors promotes differentiation. While our data supports the hypothesis that bone-resident TSP1 regulates iNOS in early OC, it is also possible that TSP1 modulation of the matrix, including stoichiometry of NCPs and protein presentation, may indirectly influence NO signaling. As ongoing research better characterizes the protein interactions in the bone matrix, the impact of matricellular TSP1 on cell signaling will be elucidated. Our data shows that exogenous TSP1 promotes osteoclastogenesis through modulation of NO signaling in OC precursors, similar to its function in endothelial cells,

platelets, and vascular smooth muscle cells through CD36 and CD47 (Chen et al., 2000; Isenberg et al., 2009; Isenberg et al., 2006; Isenberg et al., 2005). The dramatic OC phenotype of TSP1 deficiency, in contrast with the modest effects reported for receptors CD47 and CD36 (Carron et al., 2000; Kevorkova et al., 2013; Koskinen et al., 2013; Lundberg et al., 2007; Uluckan et al., 2009), suggests that TSP1 binds multiple receptors to influence OC formation. We have previously reported that CD47 promotes OC formation through inhibition of iNOS (Uluckan et al., 2009). In the setting of bone homeostasis, OCs sense increased NO produced by iNOS early in differentiation as negative feedback to regulate the extent of osteoclastic bone resorption (Zheng et al., 2006). We demonstrated in vitro that TSP1 inhibits iNOS expression in OC precursors, thereby permitting OC formation. Notably, inhibition of NO synthesis in vivo rescued the TSP1^{-/-} bone resorption defect, consistent with TSP1's influence on OC through modulation of NO signaling.

We present data to support novel roles of TSP1 that place it as a critical member of the bone microenvironment. We propose the following model: TSP1 is directionally secreted by OB into the matrix during bone formation (Cleazardin et al., 1989; Robey et al., 1989). In the bone, TSP1 promotes matrix material integrity through interactions with other essential bone matrix proteins. Moreover, the matrix-derived TSP1 acts as a paracrine signaling molecule to promote OC formation via inhibition of iNOS, thus linking OB function to OC formation via the bone matrix (**Figure 2.9 B**).

Due to its pleiotropic nature, with roles in inflammation, angiogenesis, and bone health, the TSP1-signaling axis represents a promising therapeutic target for many disease states. NOS inhibitors, including the compound L-NAME used in our study, are under clinical investigation to modulate blood pressure. Their converse, nitric oxide donors, have been in clinical use for

decades to relieve angina and hypertension. Given our data of elevated OC activity upon administration of L-NAME to TSP1^{-/-} mice, it will be important to monitor the bone health of patients administered these NO-targeted drugs long-term, especially in an elderly patient population with common bone pathological comorbidities such as osteoporosis and osteoarthritis.

Bone pathologies such as osteoporosis and bone metastasis are characterized by a disruption of healthy bone turnover leading to pathologic fracture, hypercalcemia, and nerve compression. Modulation of OCs and OBs represent an attractive point for therapeutic intervention with agents such as bisphosphonates and anti-RANKL antibody (denosumab) in clinical use (Weilbaecher et al., 2011). Our findings provide further rationale to target the TSP1-pathway, especially in comorbidities such as osteoporosis and bone metastasis. Importantly, we showed that TSP1^{-/-} mice are protected from age-associated bone loss, but the increased bone mass was accompanied by a loss in bone quality. This provides important rationale to monitor bone health, both bone density and bone quality, as part of studies investigating TSP1-pathway directed therapeutics for bone-related and other indications. As targeted drugs, including anti-CD47 antibodies, TSP1 mimetics, and NOS inhibitors, enter development and clinical use, it will be important to further investigate the role of TSP1, its receptors, and its downstream signaling molecules in bone health, to identify and monitor both harmful and positive bone effects.

Figure 2.1.

TSP1-/- mice had increased bone mass.

MicroCT analysis for calculation of bone morphological parameters: (A) Trabecular bone volume of 8-, 16-, and 32-week-old WT and TSP1-/- mice tibiae (8- and 32-week n=6/group; 16-week n=5/group). (B) Representative images of three-dimensional microCT reconstruction. (C) Cortical bone thickness and (D) total area of 12-week-old WT and TSP1-/- mice femurs (WT n=5; TSP1-/- n=4). (E) Representative images of three-dimensional microCT reconstruction. (scale bars = 500 μ m)

Figure 2.2.

TSP1^{-/-} mice had altered trabecular morphology.

MicroCT analysis for calculation of bone morphological parameters: (A) Trabeculae number and (B) trabecular spacing of 8-, 16-, and 32-week-old WT and TSP1^{-/-} mice tibiae (8- and 32-week n=6/group; 16-week n=5/group).

Figure 2.3.

TSP1 improved bone strength through effects on bone material properties.

12-week old WT and TSP1^{-/-} femurs were evaluated for structural and material strength. (A) MicroCT analysis of WT and TSP1^{-/-} mice femurs for minimum moment of inertia. Femurs were subjected to three-point bending to evaluate structural mechanical parameters (B) ultimate force and (C) yield force (ns, $p=0.0727$). (D) Yield stress was calculated to normalize for differences in cortical bone morphology (WT $n=5$; TSP1^{-/-} $n=4$). Reference point indentation was completed to evaluate local material properties: (E) initial indentation distance, (F) indentation distance increase. ($n=3$ tests/femur; WT $n=5$ femurs; TSP1^{-/-} $n=3$ femurs)

Figure 2.4.

TSP1^{-/-} mice had normal bone formation parameters.

(A) Pro-collagen type I (P1NP) was measured in the serum of fasted WT and TSP1^{-/-} mice (8-week WT n=6, TSP1^{-/-} n=5; 16- and 32-week n=5/group). (B) Double calcein labeling of 16-week old WT and TSP1^{-/-} mice. (C) WT and TSP1^{-/-} bone marrow stromal cells were differentiated into OB in osteogenic media and stained for alkaline phosphatase (ALP) and alizarin red on day 14. (D) ALP and (E) alizarin red were quantitated on day 3 and day 7.

Figure 2.5.

TSP1 deficiency resulted in decreased osteoclast function in vivo and reduced osteoclast formation in vitro.

(A) Collagen breakdown products (CTX) was measured in the serum of fasted WT and TSP1^{-/-} mice (8-week n=5/group; 16-week n=4/group; 32-week n=7/group). (B) WT bone marrow macrophages differentiated into OC in the presence of anti-TSP1 A4.1 antibody or IgM isotype control antibody at indicated days. TRAP staining for multinucleated OC at day 5 shown (representative images of n>3 biological replicates, scale bar = 0.25 mm). (C) qRT-PCR analysis for day 3 OC cultured with anti-TSP1 A4.1 or IgM control (n=3 biological replicates).

Figure 2.6.

TSP1^{-/-} mice did not have significantly reduced osteoclast numbers in vivo. (A) 8-week old (left panels) and 32-week old (right panels) WT and TSP1^{-/-} tibiae were sectioned and stained for TRAP (scale bar = 2 mm; representative images of n > 3). (B) OC per bone surface and (C) OC surface per bone surface of 8- and 32-week WT and TSP1^{-/-} mice.

Figure 2.7.

Neutralization of exogenous TSP1 prevents OC formation in wild type and TSP1^{-/-} cells. TRAP stain of WT or TSP1^{-/-} bone marrow macrophages differentiated into OC in IgM isotype control of TSP1 neutralizing antibody (clone A4.1). TRAP staining for multinucleated OC at day 5 shown. (scale bar = 0.25 mm; representative images of n>3 biological replicates)

Figure 2.8.

TSP1 regulates osteoclasts through inhibition of iNOS.

(A) qRT-PCR of iNOS from WT OC cultures in the presence of TSP1 neutralizing antibody (A4.1) or isotype control (IgM). (n=3 biological replicates). (B) WT and TSP1^{-/-} mice were administered pan-NOS inhibitor L-NAME, 40 mg/kg/day for 6 weeks, and fasted serum CTX was measured (WT n=7/group; TSP1^{-/-} n=8/vehicle, n=10/L-NAME).

Figure 2.9.

Bone-derived TSP1 is sufficient to inhibit iNOS in osteoclasts.

(A) qRT-PCR of early OC marker NFATc1 and iNOS from WT OC cultured on WT or TSP1^{-/-} bone powder (n=2 biological replicates) for 24 hours. (B) Model of the role of TSP1 in bone biology.

Table 2.1. Mechanical properties of WT and TSP1-/- femurs

Property	WT (n=5)	TSP1-/- (n=4)	p-value
Stiffness (N/mm)	58.71 \pm 14.34	70.41 \pm 7.961	0.5294
Yield displacement (mm)	0.1180 \pm 0.02089	0.1190 \pm 0.01096	0.9699
Post-yield displacement (mm)	0.2248 \pm 0.01568	0.3100 \pm 0.02640	0.0225
Energy to fracture (N*mm)	2.806 \pm 0.2241	3.940 \pm 0.4317	0.0419

Data are expressed as mean \pm SEM

Chapter 3

***Samsn1* deletion contributes to monoclonal gammopathy of undetermined significance and multiple myeloma susceptibility through effects on multiple cell types**

Abstract

Multiple myeloma (MM) is a malignancy of plasma B-cells that is invariably preceded by monoclonal gammopathy of undetermined significance (MGUS), a pre-neoplastic plasma cell proliferative disorder. Epidemiologic and population association studies demonstrated that inherited susceptibility to MM is due to an increased risk of MGUS, rather than an increased rate of transformation to overt malignancy. Therefore, prevalence of MM is likely mediated by germline MGUS risk alleles. C57Bl/KaLwRij (KaLwRij) is a spontaneous mutant mouse strain predisposed to benign idiopathic paraproteinemia (BIP), analogous to human MGUS. Using an integrative approach, we combined KaLwRij x B6 SNP analysis (418 genes) and a MM patient association study (180 genes) to identify five candidate genes likely to contribute to both murine BIP-susceptibility and human MM risk. Surprisingly, we found KaLwRij mice had complete germline deletion of one of the five candidate genes, *Samsn1*, a negative regulator of B-cell activation. *Samsn1* is expressed in hematopoietic cells, including B-cells and macrophages. Consistent with the reported inhibitory function of SAMS1 in B-cells, KaLwRij mice had enhanced B-cell responses in vitro and in vivo. We also found that SAMS1 re-expression decreases proliferation in myeloma cells, demonstrating its inhibitory function in malignant B-cells. Moreover, we found KaLwRij macrophages to have increased proliferation and markedly elevated expression of pro-tumorigenic M2 macrophage markers in vitro, and increased tumor-promoting activity in vivo, suggesting that *Samsn1* regulates macrophage activation. Thus, we identified *Samsn1* as a gene contributing to BIP-susceptibility in KaLwRij mice through mutually exclusive function in multiple cell types. It is likely that SAMS1 and its pathway members contribute to human MM progression, and may represent a point for preventative therapeutic intervention.

Introduction

Monoclonal gammopathy of undetermined significance (MGUS) is a hematological disorder characterized by an expansion of one or more antibody-producing plasma cells in the bone marrow, diagnosed by the presence of constant serum level of monoclonal paraprotein (<3 g/dL, “M-spike”). MGUS is a common syndrome of aging, with a prevalence of >3 -5% in 50-70 year olds (Kyle et al., 2006; Landgren et al., 2009). While MGUS does not present with severe clinical features, the disorder is not wholly benign, and is associated with increased fracture risk and osteoporosis (Melton et al., 2005). Most significant, MGUS is the requisite precursor to multiple myeloma (MM), and MGUS patients progress to overt malignancy at an annual rate of 1%. MM is the second most common hematological malignancy and is invariably fatal with a ~ 6 year median survival (Kumar et al., 2013). MM is characterized by an M-spike of >3 g/dL and is clinically diagnosed by the presence of CRAB symptoms: hypercalcemia, renal insufficiency, anemia, and lytic bone lesions. Because of the low rate of transformation to myeloma (lifetime risk of 10-30% (Kyle et al., 2010; Sirohi and Powles, 2006; Zingone and Kuehl, 2011)), however, MGUS is not clinically treated, and, due to lack of symptoms, most cases remain undiagnosed until the patient presents with MM.

Epidemiologic and association studies indicate germline risk alleles contribute to MM and MGUS susceptibility. Interestingly, the majority of plasma-cell intrinsic genetic events in MM cells are present in MGUS-affected B-cells (Davies 2003). There is a higher incidence for MM in African Americans that is the result of elevated risk to MGUS, rather than an increased rate of conversion from MGUS to MM (Kyle et al., 2010; Kyle et al., 2006; Landgren et al., 2006). In addition, there is a higher risk of MM in individuals with an MGUS-affected first degree relative (Jain et al., 2009; Kyle et al., 2004; Vachon et al., 2009). Seven common variants

were identified to confer a significant increase in MM risk in patients (Broderick et al., 2012; Chubb et al., 2013). Interestingly, these SNPs also confer increased risk to MGUS, (Weinhold et al., 2014), providing further evidence that MM risk is a consequence of increased risk to MGUS. These studies highlight the necessity for a better understanding of the genetic predisposition to MGUS.

A common spontaneous model for MGUS and MM is the C57Bl/KaLwRij mouse (KaLwRij). KaLwRij has been inbred separate from the other C57Bl strains, including the common wild-type C57Bl/6 (B6) strain, since approximately 1978. KaLwRij mice develop benign idiopathic paraproteineima (BIP), analogous to human MGUS, with a penetrance of ~45% by 12 months of age (Radl and Hollander, 1974; Radl et al., 1978). Affected mice may also progress to overt malignancy (~1%) with similar clinical features as MM, including severe bone pathology (Alici et al., 2004; Asosingh et al., 2000; Vanderkerken et al., 2003). The 5T myeloma cell lines were subcloned from these spontaneous myelomas, and may be transplanted into KaLwRij mice to propagate the myeloma (Radl et al., 1979). Importantly, the 5TMM cell lines will not engraft in closely related C57Bl/6 (B6) mice (Asosingh et al., 2000). Notably, while KaLwRij is a model that recapitulates many features of human disease, the genetic basis of BIP susceptibility in these mice remains unknown.

In this study, we identify *Samsn1* as a candidate gene contributing to inherited risk of KaLwRij mice to BIP, analogous to human MGUS. We used KaLwRij x B6 mouse SNP analysis and a human MM population association study to identify a candidate gene list. We found that KaLwRij mice were null for *Samsn1*, a negative regulator of B-cell activation, and show that *Samsn1* plays a role in B-cells, myeloma cells, and macrophages. We sequenced *Samsn1* in unaffected tissue from MM patients and found genetic variability that suggests that

the SAMSN1 pathway may be relevant to human disease. Together, these data suggest that *Samsn1* underlies predisposition to BIP in KaLwRij mice and that the SAMSN1 pathway may be involved in human MGUS and MM.

Materials and Methods

Mice

129S1/SvImJ, A/J, AKR/J, BALB/cByJ, CBA/J, C3H/HeJ, C57BL/6J, DBA/2J, FVB/NJ, NOD/ShiLtJ, SJL/J, and NOD-scid –IL2R γ mice were purchased from Jackson Laboratory (Bar Harbor, ME). C57Bl/KaLwRij mice were originally obtained from Dr. Gregory Mundy at Vanderbilt University. Mice were housed in shared pathogen-free conditions according the guidelines of the Division of Comparative Medicine, Washington University School of Medicine. The animal ethics committee approved all experiments.

Immunization

Mice were immunized with 50 μ g chicken gamma globulin (Biosearch Technologies, Novato, CA) in complete or incomplete Freund's adjuvant (Sigma-Aldrich, St. Louis, MO) by intraperitoneal injection at 6 (primary immunization) and 7.5 (boosting immunization) months of age. Blood samples were collected serially as indicated and stored frozen.

Immunoglobulin ELISA

Serum levels of immunoglobulins were monitored by ELISA for IgG and IgG2b according to manufacture's instructions (Bethyl Laboratories, Montgomery, TX).

Serum protein electrophoresis (SPEP)

SPEP test was performed with the SPIFE 3000 analyzer according to the manufacturer's instructions, using SPIFE SPE gel (Helena Laboratories, Beaumont, TX). The protein fractions were quantified by densitometer (QuickScan 2000, Helena Laboratories, Beaumont, TX).

Mouse phylogenetic analysis

KaLwRij genomic DNA was isolated from kidney using DNeasy blood & tissue kit as described by the manufacturer (QIAGEN, Valencia, CA). SNP array analysis was performed using the Affymetrix mouse diversity genotyping array. Sample preparation, hybridization and scanning were performed by Jackson Laboratory according to the standard Affymetrix genotyping protocol. The PHYLIP package (University of Washington, Seattle, WA) was used for the phylogenetic analysis. A distance matrix was created by the Neighbor program based on the KaLwRij and the published SNP data of other 11 strains (Didion et al., 2012; Yang et al., 2009). The neighbor-joining algorithm was used to calculate a phylogenetic tree followed by the Drawtree program for drawing the tree.

B6xKaLwRij mouse strain SNP analysis

SNP analysis was completed as previously described (Burgess-Herbert et al., 2008). KaLwRij SNPs identified from the Affymetrix mouse diversity genotyping array were compared the published SNP data of B6 mice (Yang et al., 2009). All genes annotated in Ensembl mouse genome build 37 with ≥ 5 variants were included as candidate genes for further analysis.

Human subjects

DNA for WGAA and sequencing analysis was extracted from skin cells. The study cohort consisting of 183 MM patients and 105 unaffected controls was approved by the Human Research Protection Office at Washington University School of Medicine and at the Mayo Clinic. Informed consent from the patients was obtained in accordance with the Declaration of Helsinki.

Whole-genome association analysis (WGAA)

305 MM patients and 353 unaffected volunteers were genotyped using Affymetrix 6.0 platform. Data was analyzed by logistic regression analysis, adjusted for sex and group using PLINK software (<http://pngu.mgh.harvard.edu/purcell/plink/>) (Purcell et al., 2007). SNPs in the 99th significance percentile were included in further analysis. Genes containing these SNPs were included as human candidate genes.

Sequencing of *SAMSN1* in MM patients

Coding exons and adjacent intronic regions of *SAMSN1* were sequenced in non-affected tissue from 183 MM patients and 105 unaffected volunteers by the Genome Technology Access Center at Washington University School of Medicine. PCR amplicons were constructed using the Fluidigm Access Array (Fluidigm, San Francisco, CA). Samples were harvested and indexed using the BioMark HD system (Fluidigm, San Francisco, CA). Samples were pooled into sample libraries and sequenced on a MiSeq sequencer (Illumina, San Diego, CA). Following annotation, variants in the case and control population were analyzed using logistic regression of reference allele dosage in cases and controls.

Immunoblotting

Western blot was performed as previously described (Chu et al., 2012). Antibodies: SAMSN1 (Sigma-Aldrich, St. Louis, MO), actin (Sigma), and GFP (Santa Cruz Biotechnology, Dallas, TX). Blots were incubated with horseradish conjugated secondary antibodies (GE Healthcare, Fairfield, CT) and visualized by chemiluminescence (Pierce Biotechnology, Rockford, IL).

Primary cell culture

Splenic B-cells were negatively selected via MACS with anti-CD43 beads (Miltenyi Biotec, Cologne, Germany). Cells were cultured in RPMI1650 media, 10% FBS, BME, 1% penicillin-

streptomycin and stimulated with 10 ng/ml LPS and 20 ng/ml IL-4 for 72 hours. To generate macrophages, whole bone marrow or peritoneal fluid was cultured in α MEM, 10% FBS, 1% penicillin-streptomycin, 50 ng/ml MCSF for 3 days (bone marrow macrophages) or 12 hours (peritoneal macrophages). Proliferation was measured by standard MTT assay (Sigma-Aldrich, St Louis, MO). M2 polarized macrophages were generated by stimulating day 3 bone marrow macrophages with 5 ng/ml IL-4 for 24 hours. Osteoclasts were generated by culturing bone marrow macrophages in 50 ng/ml MCSF and 50 ng/ml RANKL for 3 days. Bone marrow macrophages were generated by plating whole bone marrow cells in ascorbic acid-free α MEM, 10% FBS, 1% penicillin-streptomycin for 7 days in 5% oxygen followed by negative selection via MACS with anti-CD45 beads (Miltenyi Biotec, Cologne, Germany).

5TGM1 cell culture

The 5TGM1 murine myeloma line was originally obtained from Dr. Gregory Mundy at Vanderbilt University. 5TGM1 stably overexpressing *Samsn1* were generated using lentivirus transduction. Briefly, full-length mouse *Samsn1* cDNA was subcloned into an MSCV-PGK-Puro plasmid (MPP). To generate lentivirus, SAMS1-MPP or MPP control and lentiviral vectors pCMV Δ 8.9 and pM2G were transfected into HEK293T cells. Cell supernatant containing lentivirus was then plated on 5TGM1 cells and selected with puromycin for 72 hours. *Samsn1* expression was assayed by Western Blot. Cells were maintained in DMEM, 10% FBS, 1% penicillin-streptomycin. Proliferation was measured by BrdU ELISA according to the manufacture's instructions (Roche Diagnostics, Indianapolis, IN).

M2-macrophage injection into 5TGM1 subcutaneous tumors

1×10^6 5TGM1 cells were injected subcutaneously in the right flank of NOD-scid γ female mice. 14 days following tumor inoculation, 3×10^6 in vitro M2 polarized macrophages from B6

or KaLwRij mice were injected directly into the tumor. Tumor burden was monitored by serum murine IgG2b ELISA (Bethyl Laboratories, Montgomery, TX).

Macrophage comparison by microarray

Bone marrow macrophages were isolated from B6 and KaLwRij mice (n = 3 biologic replicates) and RNA extracted using RNeasy Mini kit (Qiagen, Venlo, Netherlands). RNA samples were submitted to the Genome Technology Access Center at Washington University School of Medicine for hybridization using the GeneChip Mouse Gene 1.0 ST array (Affymetrix, Santa Clara, CA). Data was analyzed using Partek Genomics Suite (Partek Inc., St. Louis, MO). Differentially expressed genes were based on changes of 1.5 fold or more between B6 and KaLwRij.

Quantitative reverse-transcription PCR

RNA was extracted using RNeasy Mini kit (Qiagen, Venlo, Netherlands) and cDNA generated using iScript (Bio-Rad, Hercules, CA). Quantitative PCR was completed using SsoFast EVA Green Supermix (Bio-Rad, Hercules, CA). All samples run with biological replicates of ≥ 2 .

Primer sequences (forward/reverse):

Cyclophilin: AGCATACAGGTCCTGGCATC / TTCACCTTCCCAAAGACCAC

Samsn1: TTCACGCCAAGTCCCTATGAC / TTCCCATTGGTGTTTTGCACATA

FIZZ1: GCTGATGGTCCCAGTGAATA / CGTTACAGTGGAGGGATAGTTAG

YM1: GGGCATACCTTTATCCTGAG / CCACTGAAGTCATCCATGTC

VEGF: GGAGAGCAGAAGTCCCATGA / AGATCTCCACCAGGGTCTCA

DNA amplification

Genomic DNA was extracted from tail tissue or 5TGM1 culture using DNeasy blood & tissue kit as described by the manufacturer (QIAGEN, Valencia, CA). DNA was amplified using standard

PCR and amplified products were visualized on an agarose gel stained with ethidium bromide under UV light.

Primer sequences (forward/reverse):

Gapdh: ACTTTGTCAAGCTCATTTC / TGCAGCGAACTTTATTGATG

Samsn1 exons:

exon 1: TCACCAAGTGCTTTCCTTCC / AAGGCAGCAACGTGACATAA

exon 2: AGTCTTCATCATGCCCTTGG / GTTGCTTGGCAGATGGAGTT

exon 3: AACACACACACCGCCAAAGT / CCAAACCTCTTTCCAAACACA

exon 4: TCCCTTTTCAGGTTTCATGG / CTGGGACTAAACCCCAATC

exon 5: CATCCGAGGACCACTGTTTT / TTTGCCTTTTCCTTCACCTG

exon 6: GGGTTCATCCCATTTTGTG / TCTCACCTGCTTCCTGGACT

exon 7: TTCCTGGCTTATCCTGTGCT / GGAGCATCTCTGATCTTTGGA

exon 8: TAATGGGGGAAGGGATTAGG / AATGTCCTTACCTAACTCAGAAAAAT

exon 9: AGGCAGCCTGTTGAACAAT / TGTCCCAACTTAAACAATGCAC

exon 10: AATTGCAGTTGAATTCCACAAT / CATTGCACCAGATCCCTGTA

exon 11: ATGCCCTTTAAGGCAGATCA / TGCTAACAGCCACAGTCGAT

exon 12: CCCAGCACATATGAGTGAGTACTAT / GAACTGTTCTAGGAAATCAGGTTTA

Statistics

Data are shown as mean +/- SEM. Unless otherwise indicated, experiments were analyzed using Student's t-test or 1-way ANOVA as appropriate. Sequencing results were considered to reach significance at $p < 0.05$. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$.

Results

KaLwRij mice are an inbred strain susceptible to BIP

The KaLwRij mouse strain is reported to have a high frequency of BIP (Radl et al., 1978). KaLwRij has been inbred separately from the other C57Bl strains, including B6, for over 30 years. To evaluate the relatedness of KaLwRij to B6 and other common lab strains, we performed high-density mouse SNP array analysis using KaLwRij genomic DNA. The genetic distance values were estimated based on the comparison between the KaLwRij SNP data and the published single nucleotide polymorphism (SNP) data of 11 mouse strains (Yang et al., 2009), selected for relative genetic diversity. These data demonstrated that, while closely related to B6, KaLwRij is a unique inbred strain (**Figure 3.1a**).

We hypothesized that the predisposition of KaLwRij mice to BIP and myeloma would be reflected in a unique antibody response to immune challenge. We evaluated immune response in KaLwRij and the other 11 strains of mice. We treated mice with a primary and boosting immunization, collected serial serum samples, and performed immunoglobulin ELISA and serum protein electrophoresis (SPEP) (**Figure 3.1b**). We quantitated immunoglobulin isotypes IgG (**Figure 3.1c**), IgM, and IgA. Differences in antibody isotype response among strains were highly significant, indicating that immunoglobulin response was influenced by genetic background.

In patients, SPEP is used to screen for the presence of clonal serum immunoglobulin (**Figure 1.4a**). In mice, an abnormal peak in the gamma fraction suggests an accumulation of monoclonal protein (M-spike) and indicates BIP, analogous to human MGUS. Most strains presented with an M-spike post-primary or post-boosting immunization, indicating a normal

immune response. By 18 months, however, the highest frequency of sustained M-spike was found in KaLwRij (**Table 1.1**). Notably, the M-spike incidence in its closest related mouse strain, B6, had resolved.

Our initial intention to map quantitative trait loci underlying murine BIP was confounded by the fact that the ELISA profiles we obtained appeared to reflect heterogeneity of normal immune responses rather than BIP development, and the SPEP signal took 18 months to manifest, making repeated crosses impractical.

SNP analysis identified 418 genes divergent between B6 and KaLwRij haplotypes

To identify candidate loci underlying susceptibility to BIP, we compared B6 and KaLwRij genotypes using high-density genome-wide SNP data. Of the 562,061 SNPs queried across the 19 mouse autosomes, 21,133 SNPs varied between KaLwRij and B6. 11,323 were single nucleotide variation (53.6% of variation observed), while the remaining 9,810 SNPs grouped into 3,468 blocks of two or more consecutive non-identical SNPs. Included in the observed SNP variation between B6 and KaLwRij, SNP no-calls in KaLwRij were also identified. While most of these were solitary, there were 48 groups of two or greater consecutive SNP no-calls, suggesting possible deletions affecting the locus. The largest blocks of no-calls (two instances of 6 SNPs) fall in the *Samsn1* locus that contains a total of 22 no-calls, the highest number of observed in a single gene locus.

SNP blocks of two or greater fell within a total of 1,519 gene loci, with the highest number of variants in *Ptpnrt*, containing 128 polymorphic SNPs between B6 and KaLwRij. For subsequent analysis, we used an arbitrary cut-off of blocks of five or greater consecutive SNPs, representing 56.1% of all SNPs that group in blocks of two or greater (**Figure 3.2a**). This

defined a ranked candidate gene list of 418 genes that many contribute to BIP susceptibility in KaLwRij mice (**Table 3.2**).

Association analysis of MM patients identified common variants in 180 genes

Inherited genetic susceptibility to MM is likely due to increased risk of MGUS, rather than increased risk of MGUS-to-MM transformation. We next sought to identify genetic loci contributing to increased risk of human MGUS and MM. We performed whole-genome association analysis (WGAA) in a Caucasian population of MM patients (n=305) and healthy controls (n=353) to identify common genetic variation associated with MM and its requisite precursor MGUS (**Figure 3.2b**). Relatively low sample size resulted in overall decreased significance of SNPs, and only one SNP (rs1029654 in an intergenic region) reached genome-wide significance ($p < 5 \times 10^{-8}$). Therefore, to encompass all possible genetic variation contributing to MGUS and MM risk, we queried SNPs in the 99th significance percentile as differentially represented in MM patients versus controls (343 SNPs). This identified a candidate gene list of 180 genes that may contribute to MM risk in humans (**Table 3.3**).

Integrating murine BIP and human MM genetic analyses identified 5 shared genes

To further narrow our gene list and ensure that we pursued loci of clinical relevancy, we employed an integrative cross-species approach. Combining the murine KaLwRij x B6 SNP analysis (418 genes) and human MM patient WGAA analysis (180 genes) yielded five shared genes (**Figure 3.3a**). These genes are likely to contribute to inherited susceptibility to both human MGUS/MM and murine BIP/myeloma: *Fstl14*, *Samsn1*, *Ccm2*, *Tenm2*, and *Csmd1* (**Figure 3.3b**).

KaLwRij mice have a germline homozygous deletion of *Samsn1*

MGUS is a syndrome characterized by a clonal expansion of plasma B-cells and increased monoclonal immunoglobulin production; therefore, *Samsn1*, a negative regulator of B-cell function, drew particular interest. In activated B-cells, SAMS1 is an adaptor protein in a B-cell signaling inhibitory complex, binding SHP-1/2 and the ITIM domain of PIR-B (Wang et al., 2010; Zhu et al., 2004). We hypothesized that inactivating SNPs in the *Samsn1* locus of KaLwRij would lead dysregulation of B-cells, increased B-cell activation, and subsequent BIP development.

Close inspection of the KaLwRij SNP array data at the gene locus (Chromosome 16: 75,858,793-76,022,270; SNPs encompassing Chromosome 16: 75,815,371-75,999,906) revealed that 29 no-calls in KaLwRij, suggesting a gene deletion (**Figure 3.4a**). We amplified the coding regions of *Samsn1* from DNA of KaLwRij and B6 by PCR. Surprisingly, all protein-coding exons 1-12 of *Samsn1* failed to amplify from KaLwRij germline DNA, further implying deletion of the locus (**Figure 3.4b**). To confirm loss of protein expression anticipated by gene deletion, we probed for SAMS1 in splenic B-cells treated with IL-4 and LPS. Following treatment, SAMS1 was strongly expressed in B6 B-cells, but not in KaLwRij B-cells (**Figure 3.4c**). Together, these data indicate a homozygous germline deletion of the *Samsn1* gene in KaLwRij mice.

KaLwRij mice have enhanced B-cell function

SAMS1 has been shown to regulate B-cell activity, likely through its interactions with the B-cell inhibitory protein PIR-B (Zhu et al., 2004). *Samsn1*^{-/-} mice have enhanced B-cell function compared to wild type, with increased proliferation in purified splenic B-cell culture

and increased immunoglobulin response following immunization in vivo (Wang et al., 2010). To evaluate whether KaLwRij mice showed similar increased B-cell activity, we cultured purified CD43- splenic B-cells from KaLwRij and B6 mice. Importantly, we demonstrated loss of SAMSN1 in KaLwRij cells, while purified splenic B-cells from B6 mice showed increased levels of SAMSN1 protein following stimulation with IL-4 and LPS (**Figure 3.4c**). Next, we measured proliferation of cultured primary B-cells in response to IL-4 and LPS stimulation by MTT assay. KaLwRij B-cells displayed enhanced proliferative response to B-cell activation compared to B6 (**Figure 3.5a**).

To test whether KaLwRij mice also had increased B-cell activity in vivo, we immunized 6 month old KaLwRij and B6 mice (**Figure 3.1b**) and monitored immunoglobulin response until the mice reached 24 months of age. KaLwRij mice had a significant and progressive elevation in IgG2b levels, first evident after primary immunization and continuing throughout the entirety of the experiment, more than a year following immunization (**Figure 3.5b**). Therefore, we demonstrated that KaLwRij mice showed considerable B-cell phenotypic overlap with *Samsn1*^{-/-} mice, both in vitro and in vivo.

***Samsn1* decreases KaLwRij MM cell line 5TGM1 proliferation**

The murine 5T myeloma cell lines were originally isolated from a myeloma-bearing KaLwRij mouse (Asosingh et al., 2000; Radl et al., 1979), and subsequent subclones were isolated, including 5TGM1. We confirmed *Samsn1* deletion in 5TGM1 by PCR and RT-qPCR (**Figure 4.6a-b**). Because *SAMSN1* is down regulated in many human MM cell lines (Claudio et al., 2001), and because of *Samsn1*'s role in regulating murine B-cell activation, we hypothesized that *Samsn1* was a myeloma-cell intrinsic tumor suppressor. 5TGM1 cells with stable

overexpression of *Samsn1* had decreased proliferation compared to control under both basal and IL-6 stimulated conditions (**Figure 3.6b-c**). These data suggest that *Samsn1* contributes in part to myeloma tumor growth through a cell-intrinsic mechanism, consistent with its published anti-proliferative role (Wang et al., 2010; Zhu et al., 2004).

KaLwRij mice have an altered MGUS- and MM-supportive bone microenvironment

Germline risk alleles to MGUS and MM may also influence cell types beyond pre-malignant plasma B-cells. MGUS and MM are both characterized by bone microenvironment contributions from host cells including macrophages, bone marrow stromal cells, and osteoclasts (reviewed in (Kuehl and Bergsagel, 2002)). Differential gene expression in whole bone marrow of KaLwRij and B6 mice has been previously demonstrated (Fowler et al., 2011), but individual cell-type gene expression variation has not been evaluated.

To query specific components of the BIP- and myeloma-supportive bone microenvironment we cultured primary macrophages and CD45- bone marrow stromal cells from whole bone marrow of B6 and KaLwRij mice. Microarray analysis identified 31 differentially expressed genes, including *Samsn1*, in bone marrow macrophages (**Figure 3.7a**, **Table 3.4**) and eight differentially expressed genes in bone marrow stromal cells (**Figure 3.7b**, **Table 3.5**). Notably, six genes from the macrophage analysis (*Tnfrsf26*, *Samsn1*, *Lym7*, *Sparc*, *Lrrc27*, and *Qpct*) and three genes from the stromal cell analysis (*Tnfrsf26*, *Tnfrsf23*, and *Lym7*) are included in the list of candidate genes underlying genetic susceptibility to BIP in KaLwRij mice (**Table 3.2**).

We verified the *Samsn1* expression observed in the bone marrow macrophage and bone marrow stromal cell microarrays, and confirmed that bone marrow macrophages express *Samsn1*

while bone marrow stromal cells are non-expressors (**Figure 3.7c**). To further evaluate the role of *Samsn1* in other BIP- and myeloma-supportive host microenvironment cells, we cultured primary peritoneal macrophages and differentiated osteoclasts from bone marrow macrophages. Osteoclasts expressed low but detectable levels of *Samsn1*. Peritoneal macrophages were high *Samsn1* expressors, with 70-fold higher levels than bone marrow macrophages (**Figure 3.7c**). As a population, peritoneal macrophages are more mature and have increased activation compared to bone marrow macrophages, likely due to recruitment to the peritoneal cavity in response to infection (Wang et al., 2013). These data suggest that *Samsn1* may play a role in macrophage activation.

Enhanced macrophage function in KaLwRij mice

Gene expression data from bone marrow macrophages and peritoneal macrophages suggest that *Samsn1* may contribute to macrophage function, similar to its role in B-cells. Notably, SAMS1 binding partners (PIR-B and SHP-1/2) and pathway members (Syk, PI3K, among others) in B-cells, also participate in macrophage biology (Brenner et al., 2004; Munitz et al., 2010; Xie et al., 2014). To assess macrophage activity in *Samsn1*-null KaLwRij mice, we cultured bone marrow macrophages from whole bone marrow and measured proliferation by MTT assay. We found that KaLwRij macrophages had increased proliferation compared to B6 (**Figure 3.8a**).

Tumor associated macrophages (TAMs) are established host microenvironment contributors to myeloma pathogenesis (reviewed in (Asimakopoulos et al., 2013; Berardi et al., 2013; Ribatti et al., 2013)). TAMs are broadly classified as anti-tumor M1 macrophages and pro-tumor M2 macrophages. In vitro, macrophage polarization to M1 requires stimulation with

interferon-gamma, while polarization to M2 is induced upon addition of IL-4. Under basal conditions, that is, without the addition of any stimulatory cytokines, we found that KaLwRij had significant and dramatic elevation of M2-macrophage markers FIZZ1 and YM1 in both bone marrow macrophages (**Figure 3.8b**) and peritoneal macrophages (**Figure 3.8c**). TAMs from MM patients promote tumor growth through vasculomimicry, including increased expression of pro-angiogenic VEGF. We found that KaLwRij had increased levels of VEGF transcription compared to B6 in both bone marrow (**Figure 3.8b**) and peritoneal (**Figure 3.8c**) macrophage cultures. These data suggest that under homeostatic conditions, KaLwRij macrophages are skewed towards a pro-tumor M2 polarization phenotype.

To evaluate the ability of KaLwRij M2 macrophages to promote tumor growth in vivo, we inoculated 5TGM1 myeloma cells subcutaneously in NOD-scid –IL2R γ mice. Once tumors were established (day 14), we injected B6 or KaLwRij ex vivo M2-polarized macrophages directly into the tumor and monitored tumor growth by IgG2b, the 5TGM1 Ig clonotype (**Figure 3.8d**). Tumors injected with KaLwRij M2 macrophages had significantly increased tumor growth as measured by serum IgG2b compared to tumors injected with B6 M2 macrophages (**Figure 3.8e**; representative tumors **Figure 3.8f**). Together, these findings indicate that KaLwRij macrophages have enhanced activation and contribute to myeloma pathogenesis.

***SAMSNI* genetic variation in unaffected tissue of MM**

To directly investigate the impact of *SAMSNI* to confer risk in patients, *SAMSNI* exome sequencing was performed on non-affected tissue from MM patients (n=183) and healthy controls (n=105). In total, we identified 38 SNPs contained in the protein coding regions, 5' and 3' untranslated regions (UTR), and exon/intron boundaries (**Table 3.6**). Of these, 15 SNPs only

occurred in one individual. While the majority of variants were previously known and annotated in the dbSNP database, we identified six novel SNPs, all private variants. Of the annotated SNPs, six fell in the 3'UTR, three in the 5'UTR, and two SNPs were located in exon/intron splice regions. In addition, we observed seven annotated missense variants. The remainder 20 SNPs were silent mutations or fell in intronic regions or were unannotated. Two variants reached statistical significance, rs2822790 (OR = 0.5098, $p = 0.0472$) and rs2822792 (OR = 0.5098, $p = 0.0472$). Both variants were present at lower frequency in MM cases (4.12%) than controls (8.09%), suggesting that the alternate allele may be protective. While few SNPs reached statistical significance, the variability observed in MM patients suggests that the *SAMSNI* pathway may play a role in human MGUS and MM pathogenesis.

Discussion

Using a combinatorial genetics approach, we identified genes underlying inherited susceptibility to MGUS and MM in humans and in mice. Specifically, this study identifies *Samsn1* as a novel MGUS/MM susceptibility gene, likely conferring risk via effects in both pre-neoplastic B-cells as well as host supportive macrophages. We found that KaLwRij mice are null for *Samsn1*, reported to have decreased expression in human MM cell lines (Claudio et al., 2001), thus providing compelling evidence that *Samsn1* is a permissive allele in both mouse and human pathogenesis. KaLwRij mice phenocopied the published enhanced B-cell response in *Samsn1*^{-/-} mice (Zhu et al., 2004). We further found a cell-intrinsic role for *Samsn1* as a tumor suppressor in malignant myeloma cells. We identified a novel putative role for *Samsn1* in macrophages, with KaLwRij macrophages exhibiting enhanced macrophage activation under basal conditions and increased ability to enhance myeloma growth in mice. Finally, we found two SNPs at reduced frequency in a MM patient population, providing further evidence that germline variants *SAMSNI* may confer increased risk to MGUS and MM in humans. Together, these data indicate that *Samsn1* confers risk to murine BIP and human MGUS with roles both in the pre-neoplastic B-cell and in the host macrophages.

While KaLwRij mice are a widely used spontaneous model of MGUS and MM, the genetic basis for its susceptibility to BIP remains largely unknown. SNP analysis of KaLwRij x B6 revealed more than 1000 genes containing multiple variants, including several deletions, in the KaLwRij strain. We generated a candidate gene list underlying inherited susceptibility to BIP in KaLwRij of 418 genes. Importantly, it is likely that multiple genes contribute to the

complex trait of BIP, and investigation of additional candidate genes in KaLwRij mice is underway.

To query genetic loci conferring risk to human MGUS and MM and ensure that we were pursuing genes with clinical relevancy in the KaLwRij mouse model, we completed a WGAA of human MM patients and healthy controls. Typically, sample sizes of greater than 2000 cases and controls are necessary to identify causal variants in WGAA; published MM WGAA analyzed 1675-4692 cases and 5903-10990 controls to identify risk loci with genome-wide significance (Jain et al., 2009; Kyle et al., 2004; Vachon et al., 2009). In the study described here, low sample size (205 cases, 353 controls) resulted in overall decreased significance of SNPs. To ensure inclusion of all biologically significant genetic variation, therefore, we queried SNPs in the 99th significance percentile that fell in 180 gene loci. Importantly, we identified SNPs in three of the seven previously published genetic loci associated with MGUS and MM risk (2p23.3, 3p22.1, and 7p15.3), validating our approach.

Finally, in order to identify candidate genes for biologic validation in the KaLwRij mouse model, we combined the mouse and human gene sets. This approach ensures clinical relevancy of further work in gene variant validation and investigation of biologic function. Moreover, combining the mouse and human datasets also guarantees that the human variants of interest have a murine counterpart, providing a practical, relevant, and immediate mouse model. Using this integrative approach, we identified five genes that may underlie susceptibility murine BIP and also contribute to MGUS and MM risk in patients.

Because it has been implicated in human MM cell lines and has an established role in regulating B-cell activation, we investigated the *Samsn1* locus in the KaLwRij mouse strain. Surprisingly, we found that KaLwRij had homozygous germline deletion for the coding regions

of *Samsn1*. Moreover, KaLwRij mice have a similar phenotype as the the published enhanced B-cell response of *Samsn1*^{-/-} mice with increased B-cell proliferation in vitro and enhanced and sustained antibody response in vivo (Wang et al., 2010). These data strongly indicate that loss of *Samsn1* in pre-malignant plasma B-cells confers increased risk of developing BIP in mice.

Next, we evaluated the role of *Samsn1* in myeloma cells. In human MM cell lines, *Samsn1* expression is dramatically reduced (Claudio et al., 2001), suggesting a role as a tumor suppressor in myeloma. Like the KaLwRij mouse, the KaLwRij-derived myeloma cell line 5TGM1 is null for *Samsn1*. Overexpression of *Samsn1* in 5TGM1 reduces in vitro proliferation under both basal and pro-tumorigenic conditions. These data provide compelling evidence that *Samsn1* is a myeloma-autonomous intrinsic negative regulator of tumor growth.

While it is well established that genetic risk factors contribute to susceptibility to MM, the majority of genetic alterations in MM cells are already present in MGUS plasma cells (Davies et al., 2003). These data suggest that plasma-cell extrinsic factors contribute to the conversion of MGUS to MM. Rather than being confined to the affected plasma cell, it is likely that genetic susceptibility alleles are expressed in both the pre-malignant B-cell and in supportive host microenvironment cells.

To investigate specific cell types of the bone microenvironment in BIP-susceptible KaLwRij mice, we completed gene expression analysis of B6 and KaLwRij bone marrow macrophages and bone marrow stromal cells. 31 genes were differentially expressed in B6 and KaLwRij bone marrow macrophages, and eight genes were differentially expressed in bone marrow stromal cells. Interestingly, six of the 31 differentially expressed macrophage genes (including *Samsn1*) and three of the eight differentially expressed stromal cell genes contain germline variants in KaLwRij mice as identified in the B6xKaLwRij SNP analysis. This

suggests that genetic variation likely influences these genes' macrophage expression and provides further evidence of B-cell extrinsic activity of BIP susceptibility alleles.

Samsn1 is expressed in many cells of the hematopoietic lineage, and we found that *Samsn1* is expressed by bone marrow macrophages and, to a greater extent, peritoneal macrophages from B6 mice. Increased expression in the more mature peritoneal macrophages compared to bone marrow macrophages led us to hypothesize that *Samsn1* may participate in macrophage activation via similar mechanisms as its role in B-cells.

Host tumor-associated macrophages (TAMs) have been implicated in promoting MM progression. Macrophages from MM patient bone marrow are functionally distinct from bone marrow macrophages from MGUS patients (Scavelli et al., 2008). MM tumor-associated macrophages (TAMs) support MM progression directly through elevated secretion of pro-tumorigenic factors such as IL-6 (Kim et al., 2012; Zheng et al., 2009) and by promoting angiogenesis through elevated expression of VEGF (Ribatti et al., 2006; Scavelli et al., 2008; Vacca and Ribatti, 2011).

We investigated KaLwRij macrophages to determine whether they had increased capacity to support BIP- and myeloma cells. Non-stimulated KaLwRij bone marrow macrophages and peritoneal macrophages had significantly increased macrophage activation, with elevated pro-tumorigenic M2 macrophage markers. These data suggest that, similar to its role in B-cells, *Samsn1* negatively regulates macrophage activation. Importantly, we further demonstrated that KaLwRij M2-polarized macrophages potently increased myeloma tumor growth in vivo. Together, these data indicate that KaLwRij *Samsn1*-null macrophages have enhanced macrophage response and a greater capacity to support tumor growth in vivo.

Finally, we sought to identify whether *SAMSN1* germline variants confer risk to MM in a patients. We sequenced *SAMSN1* in 183 MM patients and 105 controls. We observed 38 SNPs and identified six rare variants that are not annotated in the dbSNP database. Two SNPs had greater frequency in the control population, suggesting that they may confer MM or MGUS resistance. Further GWAS studies and sequencing of normal tissue from MM patients is necessary to validate and expand upon these findings. *SAMSN1* does not represent the only possible locus for genetic lesions; variation in other members of the SAMSN1 signaling pathway likely also contribute to MM susceptibility. Further work is necessary to elucidate binding partners and downstream effects of SAMSN1 in human cells, and in different cell types including macrophages.

Described here is a novel integrative approach to identify candidate genes contributing to risk of murine BIP and human MGUS and MM. Combining mouse and human datasets was successful in identifying genes relevant to human disease, including *Samsn1*. BIP-prone KaLwRij mice harbor a homozygous deletion of *Samsn1*, the first germline mutation identified in the KaLwRij strain. We demonstrate that *Samsn1* plays functionally important and cell-autonomous roles in multiple cell types involved in MM pathogenesis, including B-cells (as previously published), in myeloma cells, and in host supportive macrophages. Importantly, while our work focused on the role of *Samsn1*, other identified genes listed are also promising candidates to influence MM risk in multiple cell types, and work is ongoing to investigate these candidates. In particular, candidate gene *Fstl4* is especially intriguing with possible downstream effects on B-cell immunoglobulin production and M2 macrophage activation (Ogawa et al., 2008; Sierra-Filardi et al., 2011). In conclusion, this work informs and prioritizes ongoing and future human genetics studies and mechanistic studies in mice. It is highly likely that SAMSN1

and other members of its pathway play important roles in MGUS and MM pathogenesis in humans, and future work will further define the effects of *Samsn1* in myeloma progression as well as explore other risk loci contributing to MGUS and MM susceptibility.

Chapter 4

Summary of work, future directions, and clinical relevancy

Part I: Summary of work

Contributions to the understanding of Paget's "congenial soil"

The "seed and soil" hypothesis has been accepted as a model for cancer cell metastasis for decades, but, despite advances in the field's knowledge of cancer cell biology and the bone microenvironment, the definition of a "congenial soil" remains incomplete. This dissertation is focused on elucidation of this question, addressing both the composition of the bone microenvironment "soil" and whole-host "congeniality" to disease progression.

We demonstrated a novel role for anti-angiogenic and therapeutic target TSP1 in bone homeostasis in **Chapter 2**. We found that TSP1 played important roles in maintaining bone matrix integrity through effects on materials properties and overall morphology. Further, we identified TSP1 as a necessary ligand in OC formation, inhibiting iNOS and thus permitting osteoclastogenesis. Finally, we demonstrated that TSP1-deficient bone failed to inhibit iNOS in OC, leading to a model of TSP1 as a paracrine signaling molecule, coupling OB activity to OC formation. These findings have implications for TSP1-pathway directed therapeutics in trial and in clinical use to have effects on bone that will be discussed in **Part II**.

In **Chapter 3**, we focused on identifying genetic risk loci contributing to bone marrow-dependent MGUS and MM susceptibility. Using a non-biased approach, we identified large candidate gene lists that may underlie susceptibility to MGUS and/or MM in humans and BIP, the analogous disorder in mice. Combining these two datasets, we identified a candidate gene list of five genes that may contribute to both murine BIP and human MGUS. One of these genes, *Samsn1*, drew our particular attention because it is a negative regulator of B-cell activation (Zhu

et al., 2004). Importantly, we found that BIP-prone KaLwRij mice have complete germline deletion of *Samsn1*, the first germline lesion identified in these mice. KaLwRij mouse plasma B-cells had enhanced activity in vitro and vivo, consistent with the published role for *Samsn1* as a negative regulator in B-cells. KaLwRij mice have increased pro-tumorigenic M2-macrophage activation under basal conditions, and macrophages polarized to M2 have increased ability to promote tumor growth in vivo. These findings suggest a novel role for *Samsn1* in macrophages, fulfilling a similar inhibitory role as in B-cells. Finally, we demonstrated that restoration of *Samsn1* expression in KaLwRij-derived 5TGM1 myeloma cells reduced proliferation, indicating that *Samsn1* also contributes to cell-autonomous myeloma cell regulation. Thus, we demonstrated a single risk allele that participates in the negative regulation of both pre-malignant plasma B-cells and host MGUS- and MM-supportive macrophages.

While our studies focused on the role of *Samsn1* in conferring risk to murine BIP, it is likely not the only susceptibility gene contributing to the KaLwRij BIP phenotype. We will discuss the utility of further characterization of the KaLwRij mouse strain in **Part III**.

Collectively, the data presented in **Chapter 2** and **Chapter 3** contribute to our understanding of Paget's "congenial soil," providing important rationale for studying genes and proteins with pleiotropic roles in multiple cell types, locations, and pathologic states.

Part II: Future directions and clinical significance of Chapter 2

The work described in **Chapter 2** more fully characterized the role of TSP1 in bone homeostasis, but several questions regarding TSP1 function remain. As in other cell types and processes, it is likely that TSP1 plays pleiotropic, and perhaps contradictory, roles in bone.

What are the effects of bone-resident TSP1 on matrix composition and osteoclast activity?

We found that TSP1 contributes to bone quality, in part through maintenance of bone material properties. It is unclear, however, whether this phenotype is due to presence of the TSP1 ligand itself or TSP1 regulation of the stoichiometry and physical organization of other components of the bone matrix. TSP1 binds many proteins essential for bone quality, including hydroxyapatite, collagen, and numerous non-collagenous proteins including osteonectin, fibronectin, osteopontin, and proteoglycans. To determine whether presence of TSP1 influences the protein stoichiometry of bone, it would be useful to perform mass spectroscopy on devitalized bone from wild type and TSP1^{-/-} mice. Unfortunately, the technology to perform mass spectroscopy in rigid calcified bone tissue is currently unavailable. As part of an effort to map the proteins of the extracellular matrix, however, methods are being developed to digest bone lysate while maintaining protein structure with promising preliminary results (Alexandra Naba, 2013; Hynes and Naba, 2012). As these technologies become available, it will be important to evaluate mice deficient for TSP1 and other non-collagenous proteins to determine how they influence each other and, in turn, the bone extra cellular matrix to effect bone strength and osteoclast function.

A conditional TSP1 knock out in OBs would be a useful model to further evaluate the role of OB-deposited TSP1 in bone strength and quality. These mice presumably would not express TSP1 in the bone matrix or in OBs, but would have active TSP1 signaling elsewhere. While it has been shown that OBs secrete TSP1 during bone formation (Cleazardin et al., 1989; Robey et al., 1989), it is possible that other cell types also produce TSP1 for deposition in the bone matrix. If we observed TSP1 in the bone of OB-conditional TSP1^{-/-} mice, we could use the floxed TSP1 mouse crossed to cell-specific cre mice to isolate the secretory cells contributing bone matrix TSP1. To achieve a similar mouse model, we would typically create bone marrow chimeras by lethally irradiating TSP1^{-/-} mice and transplanting wild type bone marrow to measure normal osteoclast resorption of TSP1^{-/-} bone. TSP1^{-/-} mice, however, are protected from sub-lethal irradiation (Isenberg et al., 2008) and partially protected from lethal irradiation. Attempts to engraft wild type donor bone marrow have failed, resulting in a chimeric hematopoietic compartment containing both wild type and TSP1^{-/-} cells.

In **Chapter 2**, we identify that loss of TSP1 influences both bone morphology and bone matrix materials properties, and it is likely that OB expression and secretion of TSP1 plays a role in these phenotypes. While it has been established that OB secrete TSP1, it is unclear at what maturation stage OB contribute to TSP1 deposition in bone. It may be interesting to use multiple OB-lineage cre mice (osterix-cre to target early OBs, osteocalcin-cre to target mature OB, and DMP1-cre to target osteocytes) to identify the temporal requirement of TSP1 expression and secretion for matrix deposition during OB maturation. Using this OB-conditional TSP1^{-/-} model, we could evaluate bone morphology, bone strength parameters, and bone material properties as in **Chapter 2** to determine if bone strength phenotype in TSP1^{-/-} is solely contributed to osteoblastic secretion of TSP1. Moreover, beyond the scope of our work

described here, further work is necessary to understand the role of TSP1 in bone strength and fracture healing, especially given established roles for TSP1 in wound healing and angiogenesis.

In addition to its role in promoting bone quality, we hypothesize in **Chapter 2** that TSP1 deposited in the bone matrix by OB is responsible for inhibiting iNOS transcription in OC progenitors. If OB-deposited TSP1 is necessary for OC formation, we would observe a similar OC phenotype in conditional TSP1^{-/-} in OB mice as in the global TSP1^{-/-} mouse: decreased serum CTX that is rescued upon inhibition of nitric oxide synthase. These experiments would also further elucidate the role of TSP1 as a paracrine signaling molecule, coupling OB activity to OC formation via the bone matrix.

What receptors does TSP1 bind to modulate OC activity?

While we demonstrated that TSP1 is a negative regulator of iNOS in pre-OC, it remains unclear what receptor(s) it binds to exert this effect. In other cell types, both CD47 and CD36 have been implicated in TSP1-mediated inhibition of NO signaling (Isenberg et al., 2006; Isenberg et al., 2005). Importantly, TSP1 has not previously been described to modulate iNOS, though effects on eNOS and downstream molecules have been reported. Our lab previously demonstrated that CD47 negatively regulates iNOS in OC (Uluckan et al., 2009), leading us to hypothesize that it is likely a requisite receptor for TSP1-mediated NO effects. TSP1^{-/-} mice had a more severe OC phenotype in vivo than any TSP1-receptor knock out mouse models, including CD47^{-/-} and CD36^{-/-}, suggesting that TSP1 exerts its effects on OC via multiple different receptors. To test whether TSP1 binds both CD47 and CD36 to inhibit NO signaling in early OC, we could evaluate iNOS in OC from double knock-out CD47^{-/-}, CD36^{-/-} mice. If both receptors

contribute to TSP1-mediated NOS inhibition, treating OC with TSP1 neutralizing antibody should have no additional effect beyond the null phenotype.

Does TSP1 promote or inhibit metastatic tumor growth in bone?

In addition to understanding its role in homeostasis, it is important to investigate the role of TSP1 in bone during pathologic states such as bone metastasis. TSP1 was the first identified endogenous anti-angiogenic, and TSP1^{-/-} mice have increased primary tumor burden and tumor-associated vasculature (Rodriguez-Manzaneque et al., 2001). In some bone metastatic prostate cancer models however, increased TSP1 promotes tumor progression through effects on cancer cell migration (Dias et al., 2012; Firlej et al., 2011; John et al., 2010; Tuszynski et al., 1987). Interestingly, high tumor-derived TSP1 levels are a prognostic marker for cancer progression and relapse (Firlej et al., 2011). We found that the bone metastatic C42b prostate cancer cell line expressed significantly higher levels of TSP1 compared to its parental non-metastatic LnCaP cell line by RNA-seq (Li Jia, unpublished data). Similarly, but to a lesser magnitude, TSP1 expression is also elevated in bone metastatic melanoma cell line subclone B16-F10 compared to its parental non-metastatic cell line, B16-F0. We would hypothesize that high TSP1-expressing bone metastatic tumors overcome TSP1's anti-angiogenic functions and take advantage of other TSP1 functions such as mediating migration and adhesion. Once in the bone microenvironment, tumoral secretion of TSP1 will stimulate OC and initiate the vicious cycle of bone metastasis, leading to increased tumor growth. We would anticipate, therefore, that injection of TSP1-low primary tumor cell line and TSP1-high bone metastatic subclone into the mammary fat pad of mice would show similar primary tumor growth, but that the TSP1-high tumor would have

increased bone metastasis. In an intratibial model, we would anticipate that TSP1-high expressing tumors would have increased bone lesions and increased tumor burden. Subsequent overexpression and knock-down experiments in these cell lines would demonstrate sufficiency and necessity of tumor-derived TSP1 in mediating migration to and growth in bone.

While the experiments outlined address the role of tumor-derived TSP1 in tumor growth in bone, it is still unclear what role bone microenvironment TSP1 plays in bone metastasis. We hypothesized that TSP1 would promote tumor growth in bone by promoting OC activity and stimulating the vicious cycle. Our studies of bone metastasis in TSP1^{-/-} mice, however, have been largely inconclusive with TSP1^{-/-} mice having modest but non-statistically significant increases in tumor burden in aggressive intratibial models (B16-F10 melanoma and PyMMT-LV1) and an intracardiac model (B16-F10) of bone metastases, but no increases in tumor-associated osteolysis. Though we are unable to make any definitive conclusions, these data are consistent with the hypothesis that host-derived TSP1 may play different roles in tumor progression based on location and severity of malignancy. To investigate the role of TSP1 in bone metastasis, it will be necessary to use a less aggressive model, such as a orthotopic injection of PyMMT cells into the mammary fat pad of TSP1^{-/-} mice, performing tumor resection, and monitoring bone metastasis. A slower-growing tumor may allow the time necessary to uncover subtle effects of TSP1 on metastatic bone tumor burden.

Subtle effects of host TSP1 on bone metastasis may be due in part to the role of TSP1 in angiogenesis. TSP1 is largely recognized as anti-angiogenic through its interactions with CD47 and $\alpha v\beta 3$, but there are also reports that TSP1 interacts with $\alpha 6$ to promote angiogenesis. Moreover, TSP1's angiogenic properties have not been evaluated in the sinusoidal blood vessels

of the bone microenvironment. It would be useful to evaluate the effects of tumor- and host-TSP1 on angiogenesis in the experiments described above.

Clinical significance

Will pharmacologic modulation of the TSP1 pathway have effects on bone?

It will be interesting to evaluate the bone effects of TSP1-pathway directed therapeutics under development and in clinical use as anti-cancer therapeutics (TSP1 mimetics and CD47 antibodies) and to modulate blood pressure (NO donors and NOS inhibitors). We anticipate that agents that mimic TSP1 signaling (TSP1 mimetics, CD47 antagonists, and NOS inhibitors such as L-NAME used in our study) will stimulate osteoclastic bone resorption. While this increase in bone remodeling may be of minimal concern in the general population, it will be important to monitor patients at increased risk of skeletal related events such as cardiovascular disease patients presenting with osteoporosis and cancer patients at risk for bone metastasis. Our data provide rationale for TSP1-pathway inhibitory therapeutics (NO donors such as Isordil and TSP1-blocking CD47 antibodies) to reduce OC activity, especially in comorbidities such as osteoporosis and bone metastasis. As these TSP1-pathway directed therapeutics become standard-of-care, it will be important to identify and monitor both harmful and positive bone effects, including effects on bone mineral density as well as bone quality.

Part III: Future directions and clinical significance of Chapter 3

The major finding presented in **Chapter 3** is that *Samsn1* is deleted in the germline of BIP-resistant KaLwRij mice. KaLwRij have enhanced B-cell and macrophage activation, and re-expression of *Samsn1* in myeloma cells reduces proliferation. Therefore, we hypothesize that *Samsn1* contributes to genetic susceptibility of murine BIP through independent effects on multiple cell types, and that the SAMS1 pathway likely participates in human genetic risk to MGUS and MM.

Is *Samsn1* deficiency sufficient to confer increased risk of BIP in mice?

To determine whether *Samsn1* deletion is sufficient to confer BIP-susceptibility in mice, we could use a targeted *Samsn1*^{-/-} mouse model (Wang et al., 2010). To determine effects on BIP-susceptibility, we could immunize *Samsn1*^{-/-} mice and monitor SPEP response as in **Figure 3.1b**. In addition, to determine whether loss of *Samsn1* creates a myeloma-permissive microenvironment, we could inoculate *Samsn1*^{-/-} mice with 5TGM1 myeloma cells and monitor tumor growth. If *Samsn1* contributes to host BIP susceptibility and microenvironment support of myeloma, we would predict that SPEP response and tumor burden in *Samsn1*^{-/-} mice would be similar to KaLwRij.

What role do *Samsn1*-null macrophages play in BIP and myeloma?

The only published role for *Samsn1* is in B-cell activation ((Wang et al., 2010; Zhu et al., 2004)), but many cells of the hematopoietic lineage, including macrophages, are *Samsn1* expressors (BioGPS, (Claudio et al., 2001)). In B-cells, SAMS1 is a proposed adaptor protein

that interacts with the ITIM domain of PIR-B and phosphorylated SHP-1/2 to inhibit B-cell activation, likely through modulation of Lyn phosphorylation and subsequent effects on B-cell receptor (BCR) and its binding partners, including Syk, PI3 kinase, and PLC γ ((Wang et al., 2010; Zhu et al., 2004)) (**Figure 4.1**). Notably, many of these proteins participate in regulation of other hematopoietic cells, with reports of BCR complex proteins to promote and PIR-B complex proteins to inhibit macrophage activation and function (Brenner et al., 2004; Munitz et al., 2010; Xie et al., 2014). We found that KaLwRij mice have increased macrophage activation in vitro and increased pro-tumor effects in vivo, and we hypothesize that these effects are due to *Samsn1* deletion. Repeating these macrophage experiments in *Samsn1*^{-/-} mice would determine whether *Samsn1* deletion is the causal variant of the KaLwRij macrophage phenotype. Furthermore, it will also be important to identify the macrophage-autonomous role of *Samsn1*, including regulatory factors, binding partners, and downstream effects, to identify manipulatable pathways for modulating MGUS and myeloma microenvironment in a preventative setting.

Increased macrophage activation has been implicated in human MM pathogenesis (Asimakopoulos et al., 2013; Berardi et al., 2013; Ribatti et al., 2013). We found that KaLwRij mice have macrophage activation that precedes the onset of detectable BIP. We hypothesize that the increased KaLwRij macrophage activation increases BIP development, and subsequently contributes to transformation to overt myeloma. Notably, however, it is unclear both in mice and in humans whether the microenvironment promotes MGUS and myeloma development or whether microenvironment changes are a result of increased B-cell activation, representing “low-level” MGUS undetectable by current methods. It will be difficult to answer this question using current mouse models of MGUS, with the KaLwRij mouse only presenting with BIP at 2 years of age. Vitamin D deficiency and irradiation can accelerate BIP development in KaLwRij mice

(Michael Tomasson, unpublished data). We predict that chronic activation of macrophages by LPS treatment or transplant of in vitro activated macrophages may also accelerate BIP development via increased support of pre-malignant plasma B-cells. In addition, as the field identifies susceptibility loci contributing to MGUS and MM susceptibility in humans and in mice, more precise genetic models can be developed to study the pre-malignant microenvironment and evaluate the contribution of individual microenvironment cell types to disease progression, including macrophages as well as osteoclasts and bone marrow stromal cells.

What genetic variation contributes to stepwise progression of myeloma in KaLwRij mice?

We found that KaLwRij mice have homozygous germline deletion of *Samsn1*, but, while *Samsn1* likely contributes to the increased penetrance of BIP in KaLwRij, it is unlikely to be the only participating locus. Our SNP analysis identified several thousand variants between BIP-resistant B6 mice and BIP-susceptible KaLwRij mice, providing a wealth of information of genes that may contribute to BIP in mice. Particularly compelling are genes with dramatically high variation between B6 and KaLwRij, in some cases with more than 100 variant SNPs. In addition to the germline variants, we also identified differential gene expression between B6 and KaLwRij in macrophages and bone marrow stromal cells, both known to support MGUS and MM cells. Interestingly, several differentially expressed genes have genetic variation between B6 and KaLwRij, suggesting that those alleles confer risk via impacts on the microenvironment. Importantly, however, we did not identify germline genetic variation in many of the differentially expressed genes, indicating that their gene expression is dependent on non-cell autonomous effects or due to downstream effects of KaLwRij genetic variants. It is likely that

causal gene variants lie in shared or cooperative pathways to modulate B-cells and microenvironment cells to confer increased BIP risk. Bioinformatics pathway analysis of all candidate genes would be useful to identify pathways of interest for further investigation.

What role do the other candidate genes (*Fstl4*, *Ccm2*, *Tenm3*, and *Csmd1*) play in BIP risk?

In addition to whole gene-set analysis, focused examination and verification of the other four candidate genes identified in the mouse and human integrative analysis would be useful to further characterize the genetic contributions to BIP-risk in KaLwRij mice and MM-risk in humans. None of the remaining four candidate genes have been reported to play roles in plasma B-cells, myeloma cells, or host supportive cells. Based on the success of *Samsn1*, however, we anticipate that further investigation of *Fstl4*, *Ccm2*, *Tenm3*, and *Csmd1* will identify new roles for the genes in cells contributing to MM progression.

While most of the research of *Ccm2* has focused on its effects in cerebral cavernous malformations, there is evidence that it is involved in p38 MAP kinase signaling (Zawistowski et al., 2005), known to promote MM growth and a target for therapeutic intervention (Campbell et al., 2014). *Csmd* may also be a good candidate as it exerts anti-tumor effects in solid tumors, and loss of *Csmd1* is associated with poor prognosis in colorectal cancer patients (Tang et al., 2012; Zhang and Song, 2014). Relatively little is known about the function of *Tenm3*, with most of the published research focused on its role in vision. It is possible that *Tenm3* underlies a trait other than BIP-susceptibility present in KaLwRij that has not yet been characterized.

The most intriguing gene for subsequent follow-up studies is *Fstl4*. While there are no reports of *Fstl4* directly influencing cells contributing to myeloma pathogenesis, there is evidence for a downstream molecule, activin A, in multiple cell types participating in MM

progression. Follistatin inhibits the activity of activin A to promote B-cell immunoglobulin secretion (Ogawa et al., 2008), MM bone disease (Vallet et al., 2010), and pro-tumor M2 macrophage polarization (Sierra-Filardi et al., 2011). Further, the activin A pathway has direct clinical implications with increased circulating activin A correlated with increased bone disease and decreased survival in MM patients (Terpos et al., 2012). With potential roles in multiple cell types, it will be interesting to characterize the role of Fstl4 in mediating the activin A pathway in BIP-prone mice and in MGUS patients.

Sequencing of KaLwRij to identify genetic events during myeloma progression

While SNP mapping was successful in our approach described in **Chapter 3**, the approach has substantial shortcomings. SNP mapping takes advantage of “marker” SNPs that are likely in linkage with causal variants, but are not necessarily causal themselves. Moreover, SNP mapping will not identify small but biologically significant genetic lesions that may contribute to disease, especially when used to compare two closely related strains. To fully characterize the KaLwRij mouse strain, whole genome sequencing is necessary to identify all variants, including protein coding genes, non-coding RNAs, and regulatory regions. Logistically important, the closely related but BIP-resistant B6 strain is the mouse reference genome and is complete, well annotated, and publically available.

It is likely that much of the variation between B6 and KaLwRij is unrelated to inherited BIP risk. To reduce follow-up studies of non-BIP related variation, we could compare the sequence of the locus of interest from our KaLwRij colony to other isolated BIP-susceptible KaLwRij colonies. Because of the limited commercial availability, individual laboratories maintain independent KaLwRij colonies, all of which have been inbred independently for more

than 20 generations, the requisite for defining a substrain (2013). Comparing our KaLwRij substrain sequence to the sequences of other sub-strains (e.g. Croucher colony and Zannettino colony at the Garvan Institute, Mundy colony at Vanderbilt University, etc.) will help to filter variation due to genetic drift. We anticipate that all BIP-susceptible KaLwRij colonies would share alleles contributing to increased BIP risk.

While the work presented in **Chapter 3** explored the transition from a normal state to BIP, it does not address the transition to overt myeloma. The KaLwRij 5T myeloma model is the ideal system to identify plasma-cell intrinsic genetic changes between BIP and myeloma. The 5T myeloma cell lines were isolated from spontaneous myelomas arising in KaLwRij mice, and can be transplanted into syngeneic KaLwRij mice to propagate the myeloma (Alici et al., 2004; Asosingh et al., 2000; Vanderkerken et al., 2003). In this work, we utilized 5TGM1 myeloma cells to determine the role of *Samsn1* in myeloma cell proliferation. Whole genome sequencing of the 5TGM1 cell line and comparing the variation to the KaLwRij sequence would identify genes that are mutated during the BIP-to-myeloma transition in mice. Similar to comparing our KaLwRij colony sequence to other KaLwRij substrains, it would be useful to compare the 5TGM1 sequence to other available 5T cell lines (e.g. 5T33vv, 5T33vt, etc.) to filter any variation due to genetic drift. At the conclusion of these sequencing efforts, therefore, we would have a genetic model for the plasma-cell intrinsic variation that participates in the step-wise progression of myeloma: normal (B6), “MGUS” (BIP – KaLwRij), and myeloma (5T cell line).

Clinical significance:

Genetic screening and treatment strategies for high-risk MGUS patients

Despite advances in treatment, including chemotherapy, proteasome inhibitors, and bisphosphonates, that target both the malignant plasma cell as well as host supportive cells, MM remains an invariably fatal disease with a short median survival of only 6 years. MM has a requisite precursor, MGUS, that represents a unique opportunity for preventative treatment of malignancy. Despite the rapid progression of MM, however, MGUS remains non-malignant for decades, and often never transforms to overt myeloma. Because of low rates of progression, MGUS patients are not clinically treated.

Inherited risk of MM is due to increased risk of MGUS, not increased rate of transformation from MGUS to myeloma. Notably, plasma-cell autonomous genetic changes occur during the transition from normal to MGUS, with few variations between MGUS and MM affected cells (Davies et al., 2003), implicating B-cell extrinsic events in promoting malignancy. Identifying susceptibility loci to MGUS, specifically in genes that participate in microenvironment cells, will provide important data for the development of screening strategies to identify high-risk MGUS patients. Moreover, understanding malignant-cell extrinsic mechanisms that promote the progression of MGUS to MM will help to identify preventative strategies to prevent or delay onset of MM.

In our work presented here, we used a strategy to identify inherited genetic variation in MM patients compared to controls. Our analysis yielded gene candidates that act in multiple cell types, both B-cells, the current focus of the myeloma field, and in host supportive microenvironment cells. We focused our efforts on the candidate gene *Samsn1* and evaluated its

biologic function in murine myeloma cells, BIP-susceptible B-cells, and supportive macrophages. Importantly, we identified two SNPs in *Samsn1* that are underrepresented in a MM patient population. These data provide important rationale for pursuing *Samsn1* pathway genes for both screening of MGUS patients and development of preventative strategies targeted to both B-cells and macrophages.

Figure 4.1.

SAMS1 is member of the PIR-B / SHP-1/2 B-cell inhibitory complex

Following activation of the B-cell receptor (BCR), Lyn phosphorylates the ITAM for recruitment of the positive regulatory signaling complex. Lyn also phosphorylates the ITIM domain of PIR-B for recruitment of SHP-1/2 for negative regulation of B-cells. SAMS1 is likely a component of this inhibitory complex, with interactions with the PIR-B ITIM domains and SHP-1/2.

ABSTRACT

Integrins on both tumor cells and the supporting host stromal cells in bone (osteoclasts, new blood vessels, inflammatory cells, platelets and bone marrow stromal cells) play key roles in enhancing bone metastasis. Tumor cells localize to specific tissues through integrin-mediated contacts with extracellular matrix and stromal cells. Integrin expression and signaling are perturbed in cancer cells, allowing them to “escape” from cell–cell and cell–matrix tethers, invade, migrate and colonize within new tissues and matrices. Integrin signaling through $\alpha v \beta 3$ and VLA-4 on tumor cells can promote tumor metastasis to and proliferation in the bone microenvironment. Osteoclast (OC) mediated bone resorption is a critical component of bone metastasis and can promote tumor growth in bone and $\alpha v \beta 3$ integrins are critical to OC function and development. Tumors in the bone microenvironment can recruit new blood vessel formation, platelets, pro-tumor immune cells and bone marrow stromal cells that promote tumor growth and invasion in bone. Integrins and their ligands play critical roles in platelet aggregation ($\alpha v \beta 3$ and $\alpha IIb \beta 3$), hematopoietic cell mobilization (VLA-4 and osteopontin), neoangiogenesis ($\alpha v \beta 3$, $\alpha v \beta 5$, $\alpha 6 \beta 4$, and $\beta 1$ integrin) and stromal function (osteopontin and VLA-4). Integrins are involved in the pathogenesis of bone metastasis at many levels and further study to define integrin dysregulation by cancer will yield new therapeutic targets for the prevention and treatment of bone metastasis.

Introduction

The development of bone metastasis is common in many cancers, occurring in virtually all patients with multiple myeloma, in 65%–75% of patients with advanced breast and prostate cancers, and in 30%–40% of patients with lung cancer [1–3]. The consequences of bone metastases are often devastating and can cause pain, pathologic

E-mail address: kweilbae@wustl.edu (K.N. Weilbaecher).

fractures, spinal cord and other nerve-compression syndromes and life-threatening hypercalcemia [4]. Both osteolytic lesions and osteoblastic bone metastases are associated with increased OC activity and disrupted bone micro-architecture [5,6]. In the bone microenvironment, tumor cells secrete soluble factors that promote bone remodeling resulting in the release of additional bone matrix-bound growth factors which further activate OCs and osteoblasts (OB) and promote tumor growth [3,4,7–16]. Anti-resorptive therapy, e.g. with bisphosphonates or denosumab, significantly decreases skeletal complications of cancer and is a standard of care for patients with bone metastases [4,8,17–19]. In addition to their effects on bone, tumors in the bone microenvironment recruit blood vessel formation, platelets, immune cells and stromal cells that promote tumor growth and invasion in bone. Integrin-mediated cell signaling plays a critical role in many of these processes during bone metastasis, including platelet aggregation ($\alpha\text{IIb}\beta_3$), hematopoietic/immune cell mobilization (VLA-4 and osteopontin), neoangiogenesis ($\alpha\text{v}\beta_3$, $\alpha\text{v}\beta_5$, $\alpha_6\beta_4$, and β_1 integrin) and stromal function (osteopontin and VLA-4) (see Fig. 1). For these reasons, the mechanisms by which integrin signaling mediates the pathogenesis of bone metastasis have been an area of active research.

Integrin structure, activation and signaling

Integrins are heterodimeric transmembrane glycoproteins that facilitate cell–cell and cell–extracellular matrix (ECM) adhesion and cell migration [20]. Integrins recruit many intracellular signaling molecules and can activate survival, proliferation, and motility signaling pathways [21]. There are 8 beta and 18 alpha integrin subunits that assemble into 24 unique known combinations in different cell types, each characterized by distinct ligand binding specificities (including collagen, osteopontin, fibronectin, laminin, and others, depending on the integrin family), signaling abilities, and regulatory mechanisms [22]. Integrins are activated by conformational changes in the integrin extracellular domains. When the integrin α and β subunit cytoplasmic and transmembrane domains remain closely juxtaposed, the extracellular domains are held in a closed conformation. Activation by intracellular signals to the cytoplasmic tails results in separation of the α and β cytoplasmic and transmembrane domains and exposure of the extracellular ligand binding domain [23] (inside-out signaling). The

open conformation, facilitates high affinity ligand binding and triggers integrin-mediated cell signaling cascades (outside-in signaling) [24,25].

Many proteins play critical roles in the activation of specific integrins, but two cytoplasmic proteins, talin and kindlin, are necessary for inside-out signaling required for the activation of all integrin subtypes [23,26–29]. Talin binds to the proximal end of the beta cytoplasmic tail via a phosphotyrosine-binding (PTB) domain within its FERM domain [27] and links the integrin to the actin cytoskeleton [23]. Kindlin 1, 2, or 3, is necessary for talin-induced integrin activation [26,30,31]. Kindlin, like talin, also interacts with intracellular proteins resulting in cytoskeleton reorganization and adhesion [32]. G-protein coupled receptors such as the ADP receptor P2Y12, also play critical roles in the inside-out signaling required for integrin activation [25,33,34]. Structure–function analyses on β_3 integrins have shown that a membrane-proximal region is important for inside-out signaling [28,35–40].

In addition to activation by inside-out signaling, ligand binding and integrin clustering can be significantly modulated by growth factor receptor interactions and other integrin interacting proteins, as reviewed in [22,23,41]. For example, integrin associated protein, CD47, augments integrin activation and affects the ability of $\alpha\text{v}\beta_3$ integrin to cluster upon ligand binding [42]. Ligation of the integrin then stimulates outside-in signaling that leads to the activation of numerous signals critical for growth, migration, survival and other functions, including FAK phosphorylation, ERK signaling, and NF- κ B activation. Thus, integrin signaling in cancer cells and in associated stromal, endothelial and hematopoietic cells can be influenced by intracellular signaling proteins, growth factors, chemokines and other receptors that participate in regulating integrin function through effects on integrin activation, ligand binding, ligand affinity and integrin clustering.

Maintaining adhesion to the ECM, in part through integrin signaling, is critical to cell survival [43]. Altered cell–cell or cell–ECM interactions results in disruption of downstream survival signaling and anchorage-dependent non-transformed cells undergo anoikis [43]. Under normal conditions, because each cell type expresses a unique set of integrins that recognize underlying ECM ligands, this form of apoptosis ensures that detached cells do not colonize inappropriate locations [43]. Cells that resist anoikis, such as metastatic cells, take advantage of several different mechanisms so

Fig. 1. Integrin Expression During Bone Metastasis: Numerous host stromal cells types interact with tumor cells to facilitate tumor cell homing, colonization and invasion in bone. Preclinical and clinical evidence demonstrate that specific integrin expression and signaling on both tumor cells and host cells are central to facilitating bone metastasis.

that the cell can adhere to a novel ECM, including aberrant integrin expression [44], constitutive activation of molecules usually activated via integrin signaling including FAK [45], EGFR [46] and SRC [47], and lack of activation of pro-apoptotic pathways [48], among others.

The integrin family of adhesion receptors links ECM to the cytoskeleton through a complex and regulated network of activation, interaction with numerous growth factor, GPCR, chemokine and cytokine receptors and induction of complex signaling cascades.

Integrin expression and signaling on tumor cells that metastasize to bone

Tumor progression, invasion and eventual metastasis require the activity of many adhesion proteins, including the integrin superfamily. At each stage of cancer progression, subsets of integrin heterodimers are activated, providing the necessary signaling pathways for adhesion, migration and cell survival. Metastatic tumor cells show differential integrin heterodimerization and activation compared to non-metastatic tumor cells that enable the cell to home to and colonize in a metastatic site, such as the bone marrow cavity [49,50]. In order for primary epithelial cancers to metastasize, the tumor cells must become resistant to anoikis and detach from the primary tumor site ECM, enter the vasculature, and eventually colonize a distant site. Upon reaching a successful metastatic site, however, tumor cells use both anoikis and anoikis-resistance to their advantage, in some cases forming micro-metastases that are resistant to cancer treatment via integrin binding to the underlying bone ECM as reviewed in [51]. Tumor cells must also form interactions between the tumor cell and bone stroma to establish and maintain skeletal metastasis. Many integrins have been implicated in tumor cell–host bone stroma interactions during bone metastasis and tumor growth in bone (Fig. 1, Table 1), including the $\beta 1$ and $\beta 3$ integrin family members.

$\alpha v\beta 3$ is a receptor for osteopontin, fibronectin, and vitronectin, ECM proteins that are important bone matrix proteins, and $\alpha v\beta 3$ has been identified as a critical integrin in breast cancer and prostate cancer skeletal metastasis [50,52–56]. Interestingly, although $\alpha v\beta 3$ has been shown to bind to fibronectin in other locations with high affinity, tumor $\alpha v\beta 3$ integrins do not bind fibronectin in bone marrow stroma, indicating that $\alpha v\beta 3$ -expressing tumor cells bind to the bone stromal ligands vitronectin and osteopontin [57]. In breast cancer, $\alpha v\beta 3$ binding of host osteopontin is necessary for tumor cell colonization to bone [58]. Bone metastatic cells have a higher expression of $\alpha v\beta 3$ than the primary tumor [53], promoting adherence to the bone matrix by binding osteopontin expressed by bone stromal cells [58]. Breast cancer cells that overexpress $\alpha v\beta 3$ have increased levels of bone metastasis and associated tumor burden and osteolysis [52,59–62]. This overexpression of $\alpha v\beta 3$ in the tumor cells leads to increased tumor cell adhesion, migration and invasion to bone as well as enhanced OC recruitment within the bone microen-

vironment [60,61], implicating a role of tumor-specific $\alpha v\beta 3$ expression in breast cancer metastasis to bone as well as tumor-associated osteolysis. Likewise, in prostate cancer cells, active $\alpha v\beta 3$ is necessary for the adherence and migration to bone matrix proteins at early stages of skeletal metastasis. This tumor cell $\alpha v\beta 3$ integrin expression allows cancer cells to adhere to the bone matrix and interact directly with the native bone cells, OBs and OCs, as well as with the bone matrix itself [59].

The $\beta 1$ family member, $\alpha 5\beta 1$, has been identified as the primary integrin receptor for fibronectin on human bone marrow stroma [57]. $\alpha 5\beta 1$ expression on leukemia, prostate and breast cancer cells facilitates interaction with bone stroma [57,63–65]. Antibody inhibition of $\alpha 5$, $\beta 1$ or fibronectin blocks prostate cancer tumor cell binding to bone stroma, indicating necessary roles for both integrin $\alpha 5\beta 1$ on tumor cells and fibronectin on bone marrow stromal cells [57]. In breast cancer skeletal metastasis, the interaction between malignant cell $\alpha 5\beta 1$ and host stromal cell fibronectin contributes to the survival of growth-arrested tumor cells, a potential mechanism through which tumor cells can become sequestered and “dormant” within the bone marrow cavity and may later begin to proliferate to establish a skeletal metastasis [64]. Upon FGF-2 growth factor stimulation, breast cancer cells undergo growth arrest and up-regulate $\alpha 5\beta 1$ expression. In most cases, these cells die, but cells that bind fibronectin via $\alpha 5\beta 1$ and initiate cell survival signaling cascades survive [64].

Another $\beta 1$ family member, $\alpha 2\beta 1$, a collagen type I receptor, is expressed by prostate tumor cells, and its activity promotes invasion and adherence to the bone stroma. The presence of collagen I, the most abundant protein in bone, significantly increases prostate epithelial cell adhesion in culture, and antibody inhibition of integrin subunits $\alpha 2$ and $\beta 1$ significantly inhibits tumor cell binding to stroma [66]. Hall et al. showed that a skeletal metastatic prostate cancer cell line, but not cell lines that are metastatic to other organs, binds to collagen I and that this collagen I binding is $\alpha 2\beta 1$ dependent in vivo [67]. Interestingly, stromal expression of collagen I does not increase tumor growth, but instead promotes tumor cell migration [67]. Tumor cell $\alpha 2\beta 1$ binding of host bone marrow stromal collagen I activates RhoC GTPase which instigates a signaling cascade responsible for cytoskeleton reorganization, migration, and, eventually, collagen-stimulated invasion and preferential skeletal metastasis [68].

$\alpha 4\beta 1$ /vascular cell adhesion molecule-1 (VCAM-1) binding has been identified as important for cell–cell contact between $\alpha 4\beta 1$ expressing myeloma cells and VCAM-1 expressing bone marrow stroma [69]. This interaction contributes to bone tumor growth, OC stimulation and resultant osteolysis [69,70]. Likewise, epithelial tumor cells (CHO) that overexpress $\alpha 4\beta 1$ developed significantly more bone metastases than mice inoculated with CHO cells alone [71]. Bone metastases, but not other metastases, were inhibited by antibodies against $\alpha 4$ and/or VCAM-1, suggesting a role for $\alpha 4\beta 1$ /VCAM-1 binding in the skeletal metastases of solid tumors [71]. The role of integrins and chemokine cross talk in tumor cell homing to bone will be discussed later. While many aspects of tumor–bone stromal interactions remain unknown, it is clear that specific interactions between tumor cell integrins and bone stromal cell ligands are essential for successful homing and metastasis to bone.

Integrin expression and signaling in osteoclast function and bone metastasis

Bone invading metastatic tumor cells co-opt integrin signaling pathways that enhance OC function and recruitment. As part of bone remodeling, OCs bind to the bone matrix, form an actin ring mediated sealing zone, secrete enzymes and acid to degrade bone, and then migrate to a new site. Each of these functions is regulated in part by integrins located on the membrane surface of the OC, interacting with neighboring cells and with the ECM [72].

Table 1

Extracellular matrix proteins and the main integrins that participate in bone metastasis and tumor growth in bone.

Integrin	ECM ligands
$\alpha v\beta 3$	Vitronectin, osteopontin, bone sialoprotein, fibronectin, TSP-1
$\alpha 2\beta 1$	Collagen I, laminin
$\alpha 4\beta 1$ (VLA-4)	VCAM-1 fibronectin, osteopontin
$\alpha v\beta 1$	Fibronectin, vitronectin
$\alpha v\beta 5$	Vitronectin, osteonectin, bone sialoprotein, fibronectin
$\alpha IIb\beta 3$	Fibrinogen
$\beta 2$	VCAM-1, ICAM-1, fibrinogen
$\alpha 1\beta 1$	Collagen
$\alpha 5\beta 1$	Fibronectin
$\alpha 9\beta 1$	TSP1
$\alpha 6\beta 4$	Laminin, TSP-1

Several integrins are involved in OC binding to bone, including $\alpha v \beta 3$ (osteopontin, vitronectin, bone sialoprotein), $\alpha v \beta 5$ (fibronectin), and $\alpha 2 \beta 1$ (collagen) [73,74]. Of these, $\alpha v \beta 3$ is the predominant integrin found on OCs, and antibody inhibition of $\alpha v \beta 3$ inhibits OC attachment to the bone matrix as well as OC mediated bone resorption [75]. In addition, mice with targeted disruption of $\beta 3$ integrin ($\beta 3^{-/-}$) have defective OC function [76] and are protected from tumor-associated osteolysis [77]. $\alpha v \beta 3$ is responsible for mediating OC–bone recognition [53,75,78,79] and subsequent attachment to the bone matrix [75,80], signaling to create the characteristic resorptive ruffled membrane, regulation of OC spreading, and overall organization of the cytoskeleton [76,81]. Activation of $\alpha v \beta 3$ regulates OC adhesion and migration on osteopontin, important for OC polarization and bone resorption [82]. Osteopontin ligand binding of $\alpha v \beta 3$ causes a reduction of OC cytosolic calcium, inducing podosome formation and subsequent resorption [83]. In addition, $\alpha v \beta 3$ is critical for the activation of c-Src, c-Cbl, and GTPases Rho and Rac, signaling that is necessary for the cytoskeletal reorganization important in OC function [81,84,85].

OC targeted therapy is a standard of care for the treatment of bone metastasis and myeloma bone disease. Tumor cells recruit OCs resulting in bone destruction and pain [3,86,87]. Because of its known role in OC function and its high expression in skeletal metastatic tumors much research has focused on $\alpha v \beta 3$ integrin and its ligands. An important characteristic of $\alpha v \beta 3$ mediated cell adhesion, both in OCs and tumor cells, is the requirement of osteopontin, an $\alpha v \beta 3$ ligand [58]. Osteopontin is a non-collagenous bone matrix protein that is produced by OBs, OCs, and macrophages and is found in the ECM adjacent to calcified bone [88–90]. Expression of osteopontin in both the tumor cell and in the bone microenvironment can promote skeletal metastasis [91,92]. Osteopontin-deficient mice have reduced bone metastasis and tumor-induced osteolysis than wild type controls in a mouse model of tumor metastasis using syngeneic B16 melanoma cells [93,94], confirming a role for host cell osteopontin expression during bone metastasis. Recombinant osteopontin induces cell migration of B16 cells that is inhibited by repressing the ERK/MAPK pathway, suggesting that the ERK/MAPK pathway regulates bone microenvironment osteopontin levels [91]. Overexpression of osteopontin in B16 melanoma cells increases cell proliferation and migration, indicating that the ligand also plays an important role in the tumor cell itself [91]. It has been demonstrated using a prostate cancer cell line overexpressing osteopontin that tumor cell osteopontin regulates MMP-9 secretion and the subsequent CD44/MMP-9 interaction, important for the migration of prostate cancer cells, contributing to metastatic potential [95]. Osteopontin-producing tumor cells enhance osteopontin production by OBs [96] and OCs [97], stimulating osteoclastogenesis, OC adherence, migration, and bone resorption via host $\alpha v \beta 3$ binding [88,98]. Osteopontin activation of $\alpha v \beta 3$ integrin leads to downstream activation of FAK, c-Src kinase, and Ras-ERK, among other signaling molecules, resulting in cytoskeletal reorganization, focal adhesion formation, basolateral membrane differentiation, and osteoclastic resorption [59,99].

CD47, integrin associated protein, is expressed constitutively and interacts with integrins, including $\alpha v \beta 3$, as part of inside-out signaling cascades and also operates in an integrin-independent manner. CD47 plays a role in OC and macrophage biology and CD47 $^{-/-}$ mice have decreased OC number and function [100,101] which can be rescued in vitro by inhibiting nitric oxide synthase [101]. CD47 $^{-/-}$ mice have decreased bone metastases and tumor-associated osteolysis compared to wild type [101]. During the early stages of osteoclastogenesis, namely, macrophage fusion, CD47 binds with SIRP1 α , a molecule that is transiently induced in myeloid cells and that likely participates in early fusion events [102]. In the event of tumor cell metastasis to bone, however, it

has been reported that cancer cells may utilize this macrophage self-recognition signaling to fuse with macrophages [103], leading to mature OCs with tumor cell nuclei and subsequent overexpression of OC stimulation factors, thus leading to increased OC function [104].

These data underscore the importance of integrins, especially $\alpha v \beta 3$, and its adaptor proteins in OC biology and bone metabolism and point to the role of OC integrins in regulating growth of cancer cells in the bone.

Integrins and tumor neovasculature and bone metastasis

Tumor neovascularization is essential for tumor cell invasion and metastasis. Access to the host blood supply provides the tumor cells with nutrients and connects the tumor to the circulation, facilitating the dissemination of metastatic cells. The angiogenic process begins with the de-stabilization and de-differentiation of local vessels, followed by activation of endothelial cells (EC), EC migration and proliferation into the tumor ECM, and finally organization of ECs into functional vessels. The ability of tumor cells to activate the normally quiescent vasculature is proposed to be controlled by an “angiogenic switch” mechanism, whereby tumor or stromal cells induce changes in the relative balance of inducers (e.g. vascular endothelial growth factor (VEGF) or TGF β , PDGF, TNF α , bFGF) and inhibitors (e.g. thrombospondin-1 [TSP-1]) of angiogenesis reviewed in [41,105–109]. Activated platelets, tumor cells, and fibroblasts secrete many of these pro-angiogenic factors. It has recently been appreciated that macrophage lineage cells play important roles in promoting tumor-associated angiogenesis [110–113]. Bone metastasis and bone residing tumors like myeloma also modify and recruit ECs to enhance neoangiogenesis [114,115].

Many integrin heterodimers have been implicated in tumor-associated angiogenesis [41,105–109,116]. The first integrin found to regulate angiogenesis, $\alpha v \beta 3$, is expressed at high levels on tumor-associated vasculature [117,118] and tumor-associated angiogenesis can be inhibited by $\beta 3$ integrin neutralizing antibodies [119–122]. $\alpha v \beta 3$ has been specifically implicated in the angiogenesis associated with prostate cancer bone metastases; antibody inhibition of $\alpha v \beta 3$ decreases tumor-associated blood vessels in mice [123]. Interestingly, Reynolds et al. demonstrated enhanced (not reduced) tumor-associated angiogenesis in subcutaneous tumors in $\beta 3^{-/-}$ mice [124]. Elevated levels of VEGFR2 were found on tumor-associated blood vessels in $\beta 3^{-/-}$ mice, and a VEGFR2 inhibitor could block the enhanced blood vessel formation [125]. It should be noted that an inhibitor of integrin binding and signaling might have different consequences than loss of integrin expression. For example, apoptotic machinery is activated in certain cells expressing integrins that are not ligand-bound [126–129]. Recent reports that low dose integrin antagonists can increase tumor growth and angiogenesis while higher doses suppress tumor growth and angiogenesis [130] underscore the complexity of targeting $\beta 3$ integrins for angiogenesis and cancer therapy.

Another αv integrin, $\alpha v \beta 5$, also shows increased expression on tumor-associated vasculature, and $\alpha v \beta 5$ antibodies inhibit VEGF-induced tumor-associated angiogenesis [131]. In contrast, the $\beta 3/\beta 5^{-/-}$ double knockout mice show enhanced tumor-associated angiogenesis, as was seen in $\beta 3^{-/-}$ mice [125]. Several hypotheses have been proposed that reconcile the contradictory results involving the αv integrin family that outline the roles of the integrins as pro-angiogenic, anti-angiogenic, and/or working through different pathways as reviewed in [41,108]. It is clear, however, that $\alpha v \beta 3$ and $\alpha v \beta 5$ have distinct roles in regulation of tumor-associated angiogenesis and associated metastasis. The bone targeted bisphosphonate, zoledronic acid, alters EC integrin-mediated adhesion by reduced expression of $\alpha v \beta 3$ and $\alpha v \beta 5$ integrin on ECs in vitro in one observation [132]. This observation provides a possible mechanism for OC-independent anti-tumor

actions for bisphosphonates that have been reported in animal models [133–135] and clinically [136–139]. Evaluation of the effects of bisphosphonates on integrin signaling in the tumor–bone microenvironment is underway.

While much of the research in integrin-mediated angiogenesis has been focused on the α_v integrins, there is evidence that other heterodimers play a role in angiogenic regulation, particularly the β_1 and β_4 families. The β_1 integrin family ($\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_4\beta_1$) has a critical role in angiogenesis with β_1 –/– mice having severe vascular defects. $\alpha_1\beta_1$ (a collagen receptor) and $\alpha_2\beta_1$ (a laminin receptor) have been shown to be important for mediating cell adhesion in VEGF-stimulated ECs [140]. In vivo, function-blocking antibodies to α_1 and α_2 significantly inhibited VEGF-induced angiogenesis, indicating a positive regulatory role for $\alpha_1\beta_1$ and $\alpha_2\beta_1$ expression in tumor-associated angiogenesis [141]. Genetic data further support a role for the integrin $\alpha_1\beta_1$ as a positive regulator of angiogenesis as α_1 -deficient mice show reduced angiogenesis [142].

Fibronectin receptor $\alpha_5\beta_1$ has also been implicated as a positive regulator of angiogenesis: $\alpha_5\beta_1$ antagonists inhibit tumor-associated angiogenesis in mice by inhibition of EC migration and regulating proliferation and apoptosis [143,144]. Importantly, the $\alpha_5\beta_1$ antagonists did not inhibit angiogenesis induced by VEGF, indicating that the integrin $\alpha_5\beta_1$ (together with $\alpha_v\beta_3$) may act in a VEGF-independent pathway [144]. $\alpha_4\beta_1$, together with its ligand, VCAM-1, expressed in vessel mural cells, plays an important role in adhesion of ECs and vascular smooth muscle cells during blood vessel formation [145]. Both anti- $\alpha_4\beta_1$ antibodies and anti-VCAM-1 antibodies inhibit angiogenesis in vivo. Another integrin, laminin receptor $\alpha_6\beta_4$ is reported to regulate several aspects of tumor angiogenesis. Genetic studies revealed that $\alpha_6\beta_4$ promotes endothelial cell migration in culture; in addition, the integrin is involved in the translational regulation of VEGF, having a pro-angiogenic effect [146,147].

In many cases, integrins influence angiogenesis through their interaction with the integrin ligand thrombospondin 1 (TSP-1). Mice with a TSP-1 deficiency have increased tumor burden and tumor-associated vasculature, both in capillary size and number, while mice that overexpress TSP-1 have delayed or absent tumor growth and reduced tumor-associated vasculature [148]. These data indicate that TSP-1 can contribute to tumor burden via negative regulation of angiogenesis. In contrast, in a human breast cancer cell line, TSP-1 stimulation up-regulates both integrin subunit α_6 mRNA levels and protein levels which leads to increased adhesion to ECM protein laminin in vitro, suggesting that TSP-1 facilitates pathogenic angiogenesis [149]. TSP-1 also interacts with $\alpha_9\beta_1$ via its N-terminal domain and has a positive effect on proliferation and motility in culture and on angiogenesis in vivo that can be reduced by $\alpha_9\beta_1$ inhibitors. This binding of the microvasculature-associated integrin in ECs with TSP-1 activates signaling cascades including ERK and paxillin. Thus, TSP-1 can play both pro- and anti-angiogenic roles, depending on its specific integrin interaction.

The roles of integrins in tumor-associated angiogenesis are complex, not only involving integrin ligand interactions and associated signaling pathways, but also specific temporal regulation and indirect effects through proteins such as TSP-1, and are important for the progression of angiogenesis and eventual metastasis.

Integrin-hematopoietic cell interactions: tumor-induced mobilization and modulation of bone marrow cells

The bone marrow is the primary site of hematopoiesis in the adult. OBs and bone marrow stromal cells regulate hematopoietic stem cell (HSC) growth, differentiation and bone marrow retention through numerous signaling pathways including integrin VLA-4/VCAM [150], chemokine SDF-1/CXCR4, BMPs and Notch [151–156]. Hematopoietic progenitors and stem cells express the integrin VLA-4 and the

chemokine receptor CXCR4. OB and bone marrow stromal cells produce VCAM-1, SDF-1 and osteopontin, all important components of the “HSC niche” [157–159]. Integrin and chemokine signaling work in concert to promote HSC and progenitor cell homing and mobilization in the bone marrow [160]. Disruption of VLA-4/VCAM-1 and SDF-1/CXCR4 interactions results in mobilization of HSC into the circulation [159]. G-CSF mobilization of HSC acts in part through disruption of VLA-4/VCAM-1 and CXCR4/SDF1 interactions [158,161]. OC resorption can also regulate HSC mobilization and the stem cell niche [162].

Diverse integrins are expressed on hematopoietic progenitor cells in specific patterns and at distinct time points [163]. Integrins not only mediate the binding of normal progenitor cells to stroma and matrix molecules, but may also regulate expansion, maturation and differentiation of those cells [164,165]. For example, $\alpha_4\beta_1$ integrin regulates hematopoietic progenitor cell fate through changes in integrin expression and activity levels during cell maturation and differentiation into erythrocytes and neutrophils [165–167]. α_4 containing integrins mediate adhesion of hematopoietic progenitors to stromal cells likely through binding to matrix components such as fibronectin [168] or cellular receptors such as VCAM-1 [169]. The integrin subunits α_5 , α_6 and α_9 have also been shown to be expressed by progenitor cells [170–172]. Studies using blocking antibodies demonstrated that α_6 subunit cooperates in collaboration with the α_4 subunit in regulating the homing of progenitor cells [171]. $\alpha_9\beta_1$ integrin is also important for adhesion of progenitor cells to OBs in the bone marrow [172], illustrating the fact that hematopoiesis takes place in three dimensional matrices, the so-called bone marrow niches. These niches are located at the endosteum near OBs and in the vascular niche close to marrow blood vessels [173].

Tumor cells both in the bone microenvironment and at distant sites can modulate and mobilize hematopoietic progenitor and immune cells to promote bone and visceral metastasis and local tumor growth. Tumor-induced mobilization of VEGFR+ and Sca+kit-bone marrow derived cells has been implicated in enhancing distant tumor and metastatic growth [174]. These mobilized VEGFR+ cells also express $\alpha_4\beta_1$ and can migrate to sites of increased synthesis of matrix components such as fibronectin and establish a “pre-metastatic niche” that can favor tumor metastasis and growth [174]. β_2 integrins on bone marrow derived endothelial progenitors can also mediate the adhesion and VEGF-induced migration of the progenitors to the mature endothelium of actively remodeling vasculature [175].

Tumor cells from a primary lesion can act at a distance to influence bone marrow hematopoiesis through secreted factors such as the integrin ligand, osteopontin [176]. Primary epithelial tumors can instigate growth of indolent tumors through modulation of the bone marrow microenvironment and mobilization and recruitment of bone marrow cells to distant tumor sites [176,177]. McAllister et al. found that tumor secretion of osteopontin is necessary but not sufficient in xenograft models to modulate the bone microenvironment and promote bone marrow cell recruitment to tumor metastasis [176]. Pazolli et al. found that osteopontin secreted by senescent fibroblasts promoted tumorigenesis in animal models of skin cancer [178].

Thus tumors cells both in bone and at distant sites can modulate hematopoiesis in part through osteopontin and bone marrow cell integrins resulting in the mobilization and recruitment of bone marrow derived cells that will enhance local and metastatic tumor growth.

Integrins and tumor cell homing/colonization of bone

The site of metastasis is tumor cell specific depending on their integrin, chemokine receptor and cytokine/receptor expression profiles [50,179–181]. At the metastatic site, normal physiology is changed towards increased secretion of cytokines and activation of integrins to support recruitment, survival and growth of tumor cells.

Metastasizing cancer cells can co-opt the same mechanisms used in physiological hematopoietic progenitor cell homing to bone through expression of integrins and chemokines [150,152,153]. CXCR4 expressed on cancer cells can direct those cells to bone [181–186]. The migration of myeloma cells to and across bone marrow stromal cells is in part regulated by SDF-1 α /CXCR4 ligation and up-regulation of $\alpha 4\beta 1$ (VLA-4) results in adhesion of myeloma cells to the underlying bone marrow stroma [187]. Likewise, CXCR4 ligation can increase $\alpha v\beta 3$ expression and aggressiveness of metastatic prostate cancer cells, and disruption of CXCR4 can inhibit prostate cancer bone metastases [183–185].

It has recently been shown that $\beta 3$ integrin activity on circulating CXCR4-positive bone marrow derived cells is important for their migration and recruitment to sites of angiogenesis. In mice with mutated tyrosine residues “knocked in” to the $\beta 3$ integrin locus to inhibit proper phosphorylation (DiYF mice) [188], CXCR4-positive bone marrow derived cells were higher in number and defective in recruitment to subcutaneously implanted tumors or wounds, where SDF-1 levels were also lower [189]. These data demonstrate that $\beta 3$ integrin on bone marrow derived cells may be critical for the CXCR4/SDF-1 gradient, and thus may be important for localization of tumor cells to the bone microenvironment and also localization of myeloid/ECs to tumors. Interestingly, CXCR4 deletion on bone marrow cells can enhance OC activity which could counteract some of the beneficial effects of CXCR4 inhibition on bone metastases [9].

Integrins expressed by tumor cells, in concert with bone microenvironment chemokine secretion and further integrin activation, determine the osteotropic characteristics of metastasizing cancer cells and represent an ideal target for skeletal metastatic cancer therapy.

Integrins and myeloid/immune cell function during tumor growth in bone

Myeloid cell integrins are involved in tumor escape from immune responses and tumor-induced angiogenesis. Bone marrow derived myeloid cells (macrophages, monocytes, myeloid derived suppressor cells, and myeloid dendritic cells) migrate to tumors and contribute to tumor growth, invasion and angiogenesis [190–194]. Macrophages within tumors, called tumor-associated-macrophages (TAM) [127], are recruited by chemoattractants such as MCP-1 [195] secreted by the tumor and then differentiate into tissue macrophages [196]. The anti-tumor M1 phenotype represents a classical activation that is induced by pathogens, lipopolysaccharides (LPS) or interferon gamma resulting in secretion of proinflammatory cytokines such as tumor necrosis factor α (TNF α), interleukin 1 β (IL-1 β) and others. M1 macrophages can act in an anti-tumor fashion by secretion of cytotoxic cytokines and antigen presentation to lymphocytes [197]. The pro-tumor M2 phenotype, represents alternative activation induced by IL-4 or IL-10 [198]. M2 polarized macrophages promote tumor cell proliferation and survival, suppress immune responses and drive tumor neoangiogenesis [197,199–201]. Studies have shown that the TAM content of tumors and prognosis of patients are inversely correlated [192,202,203].

$\beta 2$ integrins are involved in monocyte/myeloid cell migration through endothelium and in phagocytosis, while $\beta 1$ integrins mediate adhesion to matrix proteins and the induction of inflammatory genes [204]. $\alpha 4\beta 1$ and $\alpha v\beta 3$ integrins have been implicated in myeloid cell homing, adhesion and migration to tumors. $\alpha 4\beta 1$ promotes endothelial progenitor cells and monocyte homing and adhesion to sites of active pathological angiogenesis [205]. Inhibition of $\alpha 4\beta 1$ leads to suppressed monocyte and macrophage colonization of tumors and associated vasculature and decreased angiogenesis [194].

The $\alpha v\beta 3$ integrin is down-regulated during differentiation of bone marrow myeloid progenitor cells to monocytes but induced in macrophages during inflammation [206,207]. $\alpha v\beta 3$ promotes myeloid

homing, adhesion and migration of bone marrow derived cells through the endothelium to sites of tumor angiogenesis [189]. $\beta 3$ integrins are involved in phagocytosis of apoptotic cells [208,209] and limit the secretion of inflammatory mediators [207]. Defective macrophage tumor infiltration is observed in TAM from $\beta 3^{-/-}$ bone marrow, myeloid specific $\beta 3\text{KOM}^{-/-}$ mice and in the signaling defective *DiYF* $\beta 3$ mice (mice with two mutated tyrosine residues) [111,189,210–213], suggesting that defective cytoskeletal reorganization or lack of appropriately polarized macrophages [212] within tumors may be due to $\beta 3$ integrin deficiency.

Myeloid derived suppressor cells (MDSC) [214] represent a subpopulation of immature myeloid cells that are roughly characterized by GR1+ and by the $\alpha M\beta 2$ (CD11b) integrin adhesion marker [214]. The MDSC suppress T-cell antigen receptor mediated immune responses [190] and can promote TAM M2 polarization [215]. MDSC from myeloma bearing mice had a greater capacity to become bone resorbing cells compared to MDSC from control mice [191]. The role of integrins in MDSC differentiation, recruitment and function is under investigation. Integrins are involved in monocyte/macrophage differentiation and recruitment to tumors and can influence local and metastatic tumor growth.

Integrins and tumor recruited platelets and bone metastasis

Cancer cells co-exist with platelets and mononuclear hematopoietic cells in thrombi located throughout the organs of patients with metastatic cancer [216–218]. Platelet aggregation and activation enhances tumor growth and metastasis to bone [77,219]. Platelets are anuclear metabolically active cells that are formed from bone marrow megakaryocytes. Platelet aggregation is stimulated by soluble factors such as ADP and thromboxane (TXA₂), membrane proteins, collagen or von Willebrand factor that are produced by injured endothelial, inflammatory and tumor cells. $\alpha \text{IIb}\beta 3$ plays a central role in the initiation of arterial thrombosis and platelet aggregation [220,221]. $\alpha \text{IIb}\beta 3$ integrins are expressed on the surface of megakaryocytes and platelets and are undetectable on any other non-cancerous cell type. Mice globally deficient for the $\beta 3$ integrin have prolonged bleeding times, defects in platelet aggregation and clot retraction and cutaneous and gastrointestinal bleeding, all characteristics of Glanzmann's thrombasthenia, [222] a disease characterized by functional reduction or absence of $\alpha \text{IIb}\beta 3$ in humans. Targeting $\beta 3$ integrins by monoclonal antibodies to the receptor (abciximab/Reopro) or by inhibiting the binding of the ligand fibrinogen to the receptor (tirofiban/Integrilin) are used in patients with acute coronary and cerebral vascular syndromes but have significant bleeding risks that prevent their usefulness for chronic uses such as cancer.

Tumor cell lines have been shown to induce platelet aggregation and adhesion in vitro through mechanisms involving $\alpha \text{IIb}\beta 3$ integrin, ADP, thrombin, von Willebrand factor and selectins [77,223–229]. The metastatic potential of tumor cell lines is markedly diminished in mice with defective platelet aggregation ($\beta 3$ integrin $-/-$, *Gaq* $-/-$, *Par4* $-/-$, *NFE2* $-/-$ and *fibrinogen* $-/-$) [77,219,223,226,228–244]. $\beta 3^{-/-}$ mice are protected from bone metastasis in part through a mechanism involving defective platelet aggregation [77]. Additionally, tumor cells engineered to respond to platelet-derived lysophosphatidic acid (LPA) have enhanced bone metastatic potential in mice [219]. Platelets also represent a significant source of pro-angiogenic (VEGF) and anti-angiogenic factors (TSP-1) and are recruited to tumor sites where their aggregation could affect local tumor growth [245]. Platelet-specific integrin targeting is a promising therapeutic approach for inhibiting bone metastasis, especially to prevent or slow metastasis.

In contrast to platelets, bone marrow megakaryocytes can inhibit prostate cancer tumor growth in bone [246]. Megakaryocytes can indirectly inhibit bone resorption by inhibiting OC formation [247]. The negative effect of megakaryocytes on bone resorption is likely

mediated in part through the OC inhibitory factor osteoprotegerin that is contained in secretory granules of platelets and megakaryocytes [248,249]. Adhesion of mature polyploid megakaryocytes to fibronectin is also mediated by $\beta 1$ subunit containing integrins [250,251]. Megakaryocytes may also influence bone remodeling and resorption through effects on OB proliferation that are mediated by the $\alpha 3\beta 1$, $\alpha 5\beta 1$ and glycoprotein IIb integrins [252]. Given the location of mature megakaryocytes at vascular sinusoids, they are also among the first cells to physically encounter cancer cells as they enter the bone marrow, so a direct mechanism of action involving integrin-mediated signal transduction could be involved. Interestingly, bisphosphonates (BP) increase megakaryocyte proliferation and increase the platelet concentration of the anti-angiogenic integrin ligand TSP-1 [253–255] which suggests non-OC mechanisms of BPs' action in decreasing tumor growth in bone. Thus, platelets and their megakaryocytic precursors interact with cancer cells before, during and after metastasis to bone through interactions mainly determined by integrins and their ligands.

Integrins and bone metastasis: Therapeutic aspects

Because of the wide range of functions in physiological and pathological processes, the integrin family of adhesion receptors has been adopted as a promising target for metastatic bone diseases. Several tumor cell types express an abnormal integrin profile compared to non-tumor cells [41,51,256], providing an opportunity for specific targeting. Targeting integrins on both tumor and/or host cells has proven to be effective not only in blocking local cancer progression, but also in reducing tumor cell detachment from their primary site in preclinical models [257–259].

In recent years, integrins on the tumor cells and the endothelium have been targeted by monoclonal antibodies and RGD peptides in order to reduce tumor angiogenesis [109,260]. Integrin antagonists, including humanized monoclonal antibodies, small molecule antagonists and cyclic peptides, have been developed based on the recognition sequences of integrin physiological ligands [261]. Several compounds are already in clinical use or undergoing their clinical evaluation for various diseases.

For the future treatment of skeletal metastasis, the $\alpha v\beta 3$ integrin has become an attractive target because of its expression in tumor and angiogenic cells, its role in OC differentiation and function and its role in tumor cell homing to bone [53,60,61,183,262–267]. The multiple expected beneficial effects on endothelial, cancer and osteoclastic cells instigated a significant effort to develop drug candidates that target the $\alpha v\beta 3$ integrin for therapy of skeletal complications of cancer. These strategies resulted predominantly in antagonists of $\alpha v\beta 3$, $\alpha v\beta 5$ and $\alpha II\beta 3$ integrins that showed efficacy in animal models. Peptidomimetic antagonists of the $\alpha v\beta 3$ and $\alpha v\beta 5$ integrins were successfully used to inhibit OC in vitro and to reduce bone loss in a rat osteoporosis model [268]. An active nonpeptide $\alpha v\beta 3$ integrin antagonist and anti- $\alpha v\beta 3$ antibodies were shown to hinder cancer induced bone loss [79,268–270]. It is possible that the current treatment for bone metastasis, BPs, may also exert an effect on $\alpha v\beta 3$ on both ECs [132] as well as OCs in a similar manner.

Many drugs candidates targeting integrin $\alpha v\beta 3$ have advanced to the clinic for the treatment of osteoporosis and cancer, though none have specifically targeted patients with bone metastases. A lipophilic isoester of RGD (L000845704), developed by Merck, is effective in increasing bone mineral density (BMD) in postmenopausal women [271]. Another inhibitor, RGD-mimetic cyclic peptide Cilengitide (EMD-1219974) directed at both $\alpha v\beta 3$ and $\alpha v\beta 5$ [272] and currently investigated by MerckSerono, is in advanced stages of clinical testing for the treatment of glioblastoma multiforme and is under investigation for the treatment of squamous cell carcinoma, prostate cancer, and lung cancer (Phase II).

Clinical trials of function-blocking antibodies are also ongoing, including Vitaxin (LM609), a humanized monoclonal IgG₁ antibody against the extracellular domain of the $\alpha v\beta 3$ integrin heterodimer. Vitaxin had substantial anti-angiogenic effects in preclinical models [119,262] and has shown direct anti-tumor effects as well as impaired bone resorption by inhibiting OC attachment to the bone surface [273]. Another monoclonal antibody (CNT095), directed against the αv subunit, is under development by Centocor and is in phases I–II testing for solid tumors. Two other additions to this therapeutic family are planned to be more specifically evaluated for their effects on bone metastasis [62], organic small molecule GLPG0187 [62] and peptide antagonist S247 [257].

Given the participation of the OCs, blood vessels and platelets in bone metastases, it may be beneficial to block both $\alpha v\beta 3$ and $\alpha II\beta 3$ integrins on host cells. This concept of combination inhibition relies on the common RGD ligand binding domains of $\alpha v\beta 3$, $\alpha v\beta 5$ and $\alpha II\beta 3$. In fact, many of the synthetically designed $\alpha v\beta 3$ integrin inhibitors display some selectivity towards $\alpha v\beta 5$ integrin, and, in the case of Cilengitide, this dual antagonism is part of the mechanism to treat cancer by inhibiting neoangiogenesis as well as invasion [274,275]. The strategy to combine multiple targets also bears some risks with regards to the desired high therapeutic specificity and low off-target toxicity. This issue is further complicated by the differential function of the integrins as determined by their location, expression level, activation status and ligand binding. Studies in animal models and xenograft tumor models have demonstrated that low concentrations of $\alpha v\beta 3$ integrin antagonists can act as integrin agonists [130,276,277]. Further research is necessary to identify optimal drug dosing and targeting that overcome the problem of generalized integrin inhibition to reduce or prevent skeletal metastasis.

Another area of active research in bone metastasis therapeutics is the specific targeting of integrins on HSCs or progenitors that prepare the metastatic niche and enhance bone marrow colonization by cancer cells which then instigate the vicious cycle of bone metastasis [278,279]. Interfering with integrin-mediated homing of cancer cells to the cells to the bone represents an early option for intervention. siRNA against the αv integrin subunit was used to prevent the progression of prostate cancer to bone by interfering with the ECM–integrin interaction [280]. In another approach, a disintegrin and a neutralizing antibody to VCAM-1 or its receptor $\alpha 4\beta 1$ integrin reduced metastasis of melanoma cells and diminished osteolysis by decreasing OC activity in a myeloma in vitro model [69,281]. These strategies, however, are not yet in clinical trials. An exciting new approach to cancer therapy takes advantage of the fact that cancer cells use CXCR4 and VLA-4 to home to and engraft in the marrow. HSC mobilizing agents such as AMD3100 and anti-VLA-4 targeted agents can be used to mobilize leukemia and myeloma cells into the blood from the bone marrow leading to increased sensitivity to chemotherapy [282–284] in mice. This approach is now being tested in clinical trials.

Future perspectives

Despite the high level of complexity of the integrin family, the $\beta 3$ integrin remains a major target in the search for effective therapies for skeletal metastasis. In recent years, a steady increase in knowledge has led to clinical testing of several interesting compounds. There remains, however, a lack of clarity concerning the exact roles of the integrins in different cell types. In the initiated clinical studies using $\alpha v\beta 3$ integrin antagonists, the overall effect in reducing tumor growth and pathological angiogenesis in fast progressing deadly tumors may outweigh potential undesired effects in tissues or cells other than tumor or endothelial origin. Drugs designed to tackle skeletal complications of cancer must be targeted to the bone microenvironment. This fact is underscored by

the clinical successes of the bone matrix targeted bisphosphonates and the OC targeted denosumab in treating and preventing skeletal complications of bone metastases and myeloma. A detailed understanding of the role of integrin regulation in both the metastatic tumor cells and the tumor-associated stroma will allow for a more targeted and focused approach to treat bone metastases.

Acknowledgments

The authors sincerely thank Dr. Michael Tomasson for his help, guidance and critical reading of this manuscript. This work was supported by the NIH-NIHR0152152 to KNW and by the St. Louis Men's group against cancer (SRA). JGS was supported by an IZKF start up grant from the University of Wuerzburg, Germany. SRA was also supported by the Lucille P. Markey Special Emphasis Pathway in Human Pathobiology at Washington University School of Medicine.

Sarah R. Amend

sramend@wustl.edu • (252) 349-5373

PROFESSIONAL PROFILE

Ph.D. with expertise in cancer biology, genetics, and molecular cell biology with a focus on basic research with practical translational application. Proven leadership abilities with a background in teaching, project management, and active collaboration. Committed to contributing to the understanding host contribution and response in cancer metastasis.

HIGHLIGHTS

- Ph.D. researcher with diverse background in basic laboratory science
- National Institute of Health-National Cancer Institute F31 predoctoral fellow
- Comprehensive training in translational science collaboration
- Director of Summer Focus, a youth science outreach program

EDUCATION

Ph.D. May 2014	<i>Washington University in St. Louis</i> , Saint Louis, MO Ph.D. in Molecular Genetics and Genomics
B.S. 2008	<i>North Carolina State University</i> , Raleigh, NC Bachelor of Science in Biological Sciences, minor in Genetics Summa cum laude

RESEARCH EXPERIENCE

Ph.D. candidate 2009 – present	<i>Washington University in St. Louis, Dept. of Molecular Oncology</i> Advisor: Katherine Weilbaeher, M.D. <u>Thesis</u> : Evaluating the microenvironment in bone-resident cancer: host cell contribution and susceptibility to disease <u>Project 1</u> : Role of Thrombospondin-1 as a coupling factor in bone (osteoclasts, osteoblasts, and bone matrix) under healthy and pathologic states <ul style="list-style-type: none">• Manuscript conditionally accepted at JBMR• Developed <u>novel protocols</u> to physiologically model bone microenvironment in vitro using syngeneic murine mouse serum and bone powder. Methods paper in progress. <u>Project 2</u> : Determining the genetic contributions of susceptibility to monoclonal gammopathy of undetermined significance (MGUS), the requisite precursor to multiple myeloma
--	--

	<ul style="list-style-type: none"> • <u>Discovered</u> that the gene <i>Samsn1</i> contributes to susceptibility MGUS, the requisite precursor to multiple myeloma • Implemented a <u>novel method</u> to combine low-power mouse and human genetics datasets to identify candidate susceptibility loci • Manuscript in progress.
Research assistant 2009	<i>The Jackson Laboratory</i> Laboratory of Beverly Paigen, Ph.D.; Advisor: Ron Korstanje, Ph.D.
Intern summer 2008	<ul style="list-style-type: none"> • Determined the effects of systemic vitamin D levels on susceptibility to kidney disease in mice • Identified causal SNPs in genes underlying HDL cholesterol
Research assistant 2005 – 2008	<i>North Carolina State University, Dept. of Plant Pathology</i> <ul style="list-style-type: none"> • Verified a DNA extraction technique for disease peanut plants • Managed field and greenhouse peanut crop studies
Intern 2007 – 2008	<i>Laboratory Corporation of America, Genetic Services</i> <ul style="list-style-type: none"> • Determined the efficacy of an extended carrier mutation panel high-risk populations at high risk for cystic fibrosis

COMPETITIVE RESEARCH SUPPORT

Pre-doctoral fellowship 1F31CA174096-01A1	Role: PI, 2013 - 2016 Impact score: 15; percentile: 4.0 National Institute of Health/National Cancer Institute “Evaluating the role of Thrombospondin-1 – CD47 mediated nitric oxide signaling in the vicious cycle of bone metastasis”
Training grant 5T32HL007088	Role: trainee, 2010 - 2013 Pre- and postgraduate training in Molecular Hematology National Institute of Health National Heart, Lung, and Blood Institute PI: Evan Sadler
Translational research training	Role: trainee, 2010 - 2012 Lucille P. Markey Special Emphasis Pathway in Human Pathobiology Washington University School of Medicine

CLINICAL TRANSLATIONAL EXPERIENCE

Clinical trial methodology working group 2013 - present	Collaborative think-group of clinicians, patient advocates, and biomedical researchers to accelerate investigator-driven clinical trials.
---	---

Myeloma Research Program 2011 – present	Multi-disciplinary group of oncologists, basic scientists, bioinformaticians, and clinical trialists to identify and address large-scale problems in the myeloma research and clinical communities.
Pathway in Human Pathobiology 2010 – 2012	<p><i>Lucille P. Markey Pathway in Human Pathobiology at Washington University School of Medicine</i></p> <p>Competitive didactic translational research training program</p> <ul style="list-style-type: none"> • Participated in lectures on six pathologies focused on the intersection of basic research and clinical application • Learned methods to establish dialogue between researchers and clinicians for practical implementation of scientific discovery

PROFESSIONAL EXPERIENCE

IDEA labs 2013 - 2014	<p><i>Innovation, Design & Engineering in Action (IDEA) Labs</i></p> <p>A bioengineering design incubator to invent and implement novel medical devices to solve unmet clinical problems</p> <ul style="list-style-type: none"> • Collaborate with engineers to invent the EnteroGauge, a device to measure distance during small bowel enteroscopy • Analyze product market to determine feasibility of device • Initiate patenting and commercialization of the prototype
Consultant 2013 - 2014	<p><i>Biotechnology and Life Science Advising (BALSA) Group</i></p> <p>A non-profit organization that provides short-term consulting services to organizations in biotechnology and life sciences</p>

LEADERSHIP EXPERIENCE

Summer Focus Director 2012 – 2013	<p><i>Young Scientist Program</i></p> <p>Summer Focus provides high school students with funded full-time research internships at the Washington University Medical Center with the mission to attract students from disadvantaged backgrounds to STEM careers by emphasizing hands-on research and individual mentoring.</p> <ul style="list-style-type: none"> • Oversaw a corps of >100 volunteers • Managed the program budget (~\$40,000) • Generated a Summer Focus project charter, a living document outlining key personnel, responsibilities, budget, and policies • Facilitated an active network of university administration, faculty advisors, lab personnel, and program leadership • Implemented a leadership team for delegation of specialized tasks (assistant director, course instruction, communications)
---	---

- Teaching Assistant** *Washington University in St. Louis, Department of Genetics*
2011 Graduate-level advanced genetics course
- Led weekly discussion groups and study sections
 - Lectured on basic genetics concepts
 - Facilitated faculty lectures
- Laboratory mentor** *The Jackson Laboratory and Washington University in St. Louis*
2009 Individual lab mentoring for a 2 high school students, 2
2011 - 2013 undergraduates, and 1 graduate rotation student
- Developed challenging short-term independent projects
 - Promoted individual experiential learning

PROFESSIONAL HONORS

- 2012 American Bone and Mineral Society Young Investigator travel grant
International Bone & Mineral Society/Cancer Induced Bone Disease travel grant
European Calcified Tissue Society/ASBMR Young Investigator Award
- 2008 James P. Murphy Memorial Scholarship at The Jackson Laboratory
The Horace W. Goldsmith Foundation award at The Jackson Laboratory
Center for Creative Leadership certification
- 2007 Certificate of Excellence, School of Life Science at the University of Dundee
- 2005-08 Caldwell Fellow, North Carolina State University
- 2004-08 University Honors Program, North Carolina State University
- 2004 Girl Scout Gold Award

PUBLICATIONS

Manuscript Conditionally Accepted:

Amend, SR, O Uluckan, M Hurchla, D Leib, D Novack, M Silva, W Frazier, K Weilbaecher. Thrombospondin-1 regulates bone homeostasis through effects on bone matrix integrity and nitric oxide signaling in osteoclasts. *Journal of Bone and Mineral Research*.

Manuscripts in preparation:

Amend, SR, L Chu, L Lan, D Serie, C Vachon, L Lu, R Vij, G Colditz, K Weilbaecher, MH Tomasson. Deletion of *Samsn1* underlies genetic susceptibility to monoclonal gammopathy of undetermined significance (MGUS) in mice.

Amend, SR, R Zeng. Novel methods for physiologic cell culture of murine osteoclasts using syngeneic serum and bone.

Peer-reviewed manuscript:

Leduc, MS, M Lyons, K Darvishi, K Walsh, S Sheehan, **S Amend**, A Cox, M Orho-Melander, S Kathiresan, B Paigen, and R Korstanje. The Mouse QTL Map Helps Interpret Human Genome-Wide Association Studies for HDL Cholesterol. 2011. *Journal of Lipid Research*.

Invited review:

Schneider, JG, **SR Amend**, KN Weilbaecher. Integrins and bone metastasis: Integrating tumor cell and stromal cell interactions. 2010. *Bone* 48(1):54-65.

NATIONAL and INTERNATIONAL CONFERENCE PRESENTATIONS

Invited talks:

Amend, S, L Chu, D Serie, C Vachon, L Lu, R Vij, G Colditz, K Weilbaecher, and M Tomasson. December 2013. Deletion of *Samsn1* underlies genetic susceptibility to monoclonal gammopathy of undetermined significance (MGUS) in mice. *American Society of Hematology Annual Meeting*, New Orleans, LA.

Amend, S, O Uluckan, M Hurchla, L Jia, W Frazier, and K Weilbaecher. November 2012. Thrombospondin-1 contributes to the vicious cycle of bone metastasis in both the tumor and host microenvironment compartments. *International conference on Cancer Induced Bone Disease*, Lyon, France.

Plenary abstracts:

Amend, S, L Chu, D Serie, C Vachon, L Lu, R Vij, G Colditz, K Weilbaecher, MH Tomasson. November 2013. *Samsn1* underlies genetic susceptibility to MGUS, the requisite precursor to multiple myeloma. *International Conference CIBDS*, Miami, FL.

Amend, S, O Uluckan, M Hurchla, L Jia, W Frazier, and K Weilbaecher. October 2012. Thrombospondin-1 regulates bone density in healthy and skeletal metastatic states by regulating osteoclast-osteoblast coupling. *ASBMR*, Minneapolis, MI.

Amend, S, O Uluckan, M Hurchla, L Jia, W Frazier, and K Weilbaecher. July 2012. Thrombospondin-1 regulates bone density through iNOS-mediated effects on nitric oxide signaling on osteoclasts. *International Workshop on Advances in the Molecular Pharmacology and Therapeutics of Bone Disease*, Oxford, United Kingdom
